NUMBER 1

RECOLLECTIONS AND LETTERS OF SIR JAMES MACKENZIE*

JOSEPH H. PRATT, M.D.†

BOSTON

THE career of James Mackenzie is without a parallel in medical annals, and the facts of his life read like a romance. A poor boy, the son of a Scottish farmer, he left school at the age of fifteen. For him schoolbooks had no attraction, but the colored lights in the windows of a chemist's shop lured him, and he became an apothecary's apprentice. That this was not the best foundation for medical studies everyone must agree. Finally he realized his mistake, and at the relatively advanced age of twenty-one he began his medical studies in the University of Edinburgh. He graduated in 1878, and after serving a year's residence in the Royal Infirmary became an assistant in a medical "firm" in the manufacturing city of Burnley, England. This firm had been established about eighty years earlier, and the successors of the founders carried on a large general practice. There was nothing in his environment to stimulate him to do anything more than conscientious routine work in the diagnosis and treatment of cases representing the entire range of medical practice, yet he developed new methods of clinical investigation and made important discoveries in diseases of the heart and in the nature and significance of pain in visceral disease. He showed that the sphygmograph, which had come to be regarded as a physiological toy, could be made to yield information of great clinical value.

After twenty-eight years of general practice, he broke all precedents by moving from a provincial English town to London, he became a consulting physician, limiting his practice to diseases of the heart. He had no school or hospital connections, and was practically a stranger in the metropolis, his name was almost unknown to London physicians. Every avenue leading to advancement seemed closed to him. He had a wife and two children to support, and at first there were no patients. His biographer says that his income dur-

ing that first year in London was only £114. Then, some time during his second year, he awoke to find himself famous. His book on the heart had a great sale, and his name became a household word. Patients in large numbers were referred to him by physicians in this country and Canada as well as in Great Britain. A new department for cardiac disease was established for him at the great London Hospital. He was made a fellow of the College of Physicians and a fellow of the Royal Society, and the honor of knighthood was conferred upon him by the King. At the high tide of prosperity he gave up everything he had obtained in London and moved to the small town of St Andrews in Scotland, to establish an institute for clinical research, largely at his own expense. Increased honors reached him there, and he was made Physician to the King in Scotland. In August, 1924, because of ill health he retired to London, where he passed the last months of his life. His death on January 25, 1925, was due to disease of the heart, the organ with which his name will always be associated. His mental activity and energy continued to the last, and he wrote the final sentences of a book summarizing five years' work at St Andrews less than forty-eight hours before he succumbed to coronary thrombosis.

Sir James Mackenzie made three visits to America; the first, a nonmedical trip, in 1880 after recovery from typhoid fever, when he traveled as far west as Yellowstone National Park. Since he had no money, being only two years out of medical school, he probably accompanied a patient. The second trip was in 1906, when he attended the meeting of the British Medical Association in Toronto. He was then a general practitioner, and he came and went largely unnoticed by the recognized leaders of the profession. During his third visit in 1918 he was everywhere received as a distinguished representative of British medicine. He was selected at that time by the British government as a member of a small commission of medical men to visit the United States, and he attended

*Gerrish Memorial Lecture delivered at the Central Maine General Hospital, Lewiston, Maine May 24, 1940.

†Clinical professor of medicine, Tufts College Medical School, physician-in-chief, New England Medical Center.

among other meetings those of the Massachusetts Medical Society and of the American Medical Association. He was always a general practitioner at heart. When in Boston in 1918, as he was leaving my home in Brookline, we met my friend and neighbor, Dr. George K. Sabine, a leading family doctor in that town. Sir James grasped his hand warmly and said it was indeed a pleasure, after associating only with surgeons and consulting physicians, to meet one of his own kind, a general practitioner.

My first acquaintance with Dr. Mackenzie was made at the Toronto meeting in 1906, which I attended with my friend, Dr. Henry A. Christian. Although representatives of British medicine whose reputations were world wide were at the meeting, the one who impressed us most was the general practitioner from Burnley, James Mackenzie. He was then fifty-three years of age. We saw a tall, well-built man with a fine head, noble brow and kindly eyes, who spoke with a contagious enthusiasm. Two symposiums were held by the medical section; one dealt with blood pressure, the other with heart block. Mackenzie read a paper in each of these. This was certainly an unusual distinction. On the same program were such names as Ludwig Aschoff, Sir Clifford Allbutt, Sir William Broadbent, and George A. Gibson, of Edinburgh. Mackenzie's paper was the third in a series on heart block that he had written within a short period. It represented the results of long and faithful investigation by means of simultaneous records of the jugular and radial pulses. He reported a most unusual case of transient heart block that occurred when the patient swallowed, and proved its existence by clear, convincing tracings. After his death the writer of a memorial sketch¹ in the *Lancet* stated that it was this paper that first made his labors clear "to anything like a large audience." When I was in London two years later a leading physician referred to Mackenzie in a condescending manner as "Heart-block Mackenzie." At the Toronto meeting, Mackenzie also demonstrated his ink-writing polygraph, newly invented, which enabled him to make continuous pulse tracings of the radial and venous pulse for many minutes. The jugular pulse tracings made with other types of apparatus, which two physicians presented, did not compare with those shown by Mackenzie. In fact they were so poor that definite interpretation of the tracings was difficult if not impossible.

After the Toronto meeting Mackenzie came to Boston, accompanied by his friend, Dr. Arnold Lea. He wished particularly to meet Professor William T. Porter of the Physiological Depart-

ment at the Harvard Medical School, with whose important paper on the filling of the heart he was familiar. It was characteristic of him then, as it had been in earlier years, to seek help from physiologists. Dr. Porter had organized and developed a company which made physiological apparatus for the use of students in medical schools. Unforeseen obstacles prevented the fulfillment of Dr. Mackenzie's hope that his ink-writing polygraph might be manufactured by Dr. Porter's instrument makers. During this visit Mackenzie gave a demonstration of his instrument one evening after dinner to a group of young men that I assembled.

He was particularly interested in a case of mitral stenosis, with absolutely irregular pulse, at my outpatient clinic at the Massachusetts General Hospital, and he referred to it in a letter written a year later. He pointed out to those gathered about him that the typical presystolic murmur of mitral stenosis was absent, and that it is never found after the auricular wave has disappeared from the venous pulse.

In 1902 he published his first book, *The Study of the Pulse*, which had only a small sale in England and in this country. This book, considered by some his greatest and most original work, contained reproductions of over three hundred carefully analyzed tracings that he had made in cases observed in his private practice. These consisted of records of the arterial, venous and hepatic pulses and many cardiograms. Nothing to compare with this collection had ever been published. He began to make tracings of the jugular pulse in 1891. For years he used for this purpose a Marey tambour attached to a Dudgeon sphygmograph, a simple equipment that could be carried in the pocket. His first paper—and an excellent one—dealing with the venous pulse was published in 1892 in Volume I of the *Journal of Bacteriology and Pathology*. He showed clearly that Friedreich's interpretation of the waves in the venous pulse, universally accepted as correct for thirty years, was wrong, in that the wave caused by the contraction of the auricle was attributed to the ventricle. Mackenzie proved that this error was due to incorrect timing of events in the cardiac cycle. In the preface to his book, *The Study of the Pulse*, he writes:

This volume has been written amid the distractions of the life of a busy general practitioner. I have seldom been able to give an uninterrupted hour's study to the subject. While working out some argument, interruptions have often been fatal to its completion, as it has been days and even weeks before I have again been able to resume it. While the working out of these problems has been a source of interest and of

pleasure, the labour of writing them out has been a weariness to the flesh. This I do not offer as an excuse, but as an explanation.

The book had been recommended to me by Dr Walter I. Steiner, of Hartford, Connecticut, who was possibly the first American to recognize its value, but I had not read it. I told Dr Mackenzie during his Boston visit that I was going to buy his book. He replied "Don't. Nobody does. I have a shed full at home and will send you a copy." Instead of mailing the book, he waited until he could send it by a messenger. Some months later Dr. George W. Ross, of Toronto, arriving in Boston from England, brought me the book. Ross had spent a short time in Burnley with Mackenzie, observing his work, and was probably the first physician from this side of the Atlantic to visit Burnley for the purpose of learning Mackenzie's methods. There he could get a knowledge of certain aspects of cardiac disease not attainable elsewhere in the world. What Mackenzie had to offer can be appreciated from the following letter written in Burnley, and dated May 20, 1907:

I am very glad things are prospering with you, though I am sorry you could not come and see Burnley. My reason for regret is that I have here such a wonderful selection of cases illustrating a great many forms of heart change, unsuspected and unrecognized, and I fear much that my removal will take me out of touch of these cases. Still I shall be glad to renew our acquaintance when you come to London next year.

I have just returned from attending the meetings of a newly formed Association of Physicians in London. I expounded some new views as to the meaning of the continual irregular heart and the direct causes of heart failure in these cases, which views were received appreciatively, but as my audience did not appreciate my facts, I fear they were not convinced. I saw Osler there and also your adoring friend Martin of Montreal, who hopes to spend next Thursday night here before sailing from Liverpool. I have also had a pleasant visit from Dr. Grosh of Toledo, who is to be expounding some views on the venous pulse at the meeting on June 6th at Atlantic City.

My book that Ross left you is sadly behind the times, but it gives an idea how to set about this sort of work. Your hands are too full with your own line of study and as this requires a long and painful training, you might start some of your promising juniors—it will amply repay them for the trouble. I find Ross a most apt pupil, and with him in Canada and Grosh in Toledo, I am hoping that these two sources will lighten a big lump of your vast continent. They are also promising good things at Johns Hopkins.

Remember me to Joslin, Christian, and the other bright spirits who made my visit to Boston so delightful. Arnold Lea occasionally visits me, and we recount our Boston experiences with great gusto—particularly the charming Williams' most interesting yarns.

Osler appears to have been the first physician of distinction in England to appreciate Macken-

zie's worth, and we learn from Cushing's *Life of Sir William Osler* that very shortly after he settled in England, in July, 1905, he made a visit to Burnley. Of this, Mackenzie wrote Cushing. "One of Osler's great charms was the kindly interest he took in obscure workers in any field of medicine, and in 1905 when I was a general practitioner in a remote town in Lancashire he paid me a visit; and though my work was not that in which he was directly interested yet his appreciation was in itself a very great encouragement." Mackenzie told me that he had demonstrated to Osler at that time a case of mitral stenosis in which the typical presystolic crescendo murmur had disappeared as a result of paralysis of the auricle,—indicated by an absence of an *a* wave in the venous tracing,—but that he could not convince Osler of the correctness of his observation.

Possibly about the same time, but probably a year or two earlier, Mackenzie received a visit from the great Dutch physician, Wenckebach, whose contributions to a knowledge of the arrhythmias rank with his own. In Wenckebach's monograph on this subject published in 1903 he gives Mackenzie great praise. The latter in turn thought so highly of Wenckebach's work that he induced a Burnley ophthalmologist, Dr. Snowball, to translate the German text into English, and secured its publication. This book, well printed and attractively bound, probably had a very small sale, because the general medical world at that time knew too little of the subject to appreciate its importance.

Osler was also the first to bestow praise on Mackenzie at a large medical gathering. At the Congress of American Physicians and Surgeons, held in Washington in May, 1907, in the course of an address on "The Evolution of the Idea of Experiment in Medicine" he said, "In every country there will be found strong men like Weir Mitchell, Mackenzie of Burnley, and Meltzer and Christian Herter who find it possible to combine experimental work with practice."

Mackenzie probably made the bold decision to settle in London in the hope that he could find able young men who would use the new methods he had devised, and he doubtless thought that if he were located in a large medical center he would have greater opportunities for carrying on investigations with the aid of such outstanding men of science as Cushny, the pharmacologist, and Arthur Keith, the anatomist. He would also be in a better position to acquaint the medical profession with the new knowledge of heart disease that he had brought to light.

Mackenzie was a true missionary of science, with a zeal that could not be quenched by opposition,

or what is more difficult to bear, indifference. In Manchester, the nearest medical center to Burnley and the seat of a medical school (Owen College), he tried in vain to get his methods adopted. He once told me that for fifteen years he attempted to interest the physicians in Manchester by giving papers and demonstrations. There would be no discussion. After the meeting he would find himself alone in the room. He would pack up his polygraph and tracings and retrace his steps to Burnley, forty miles distant.

The next letter I have preserved was written on November 5, 1907, shortly before he left Burnley to work in the larger field of London.

I was glad to hear from you again, and pleased with the idea that you intend taking up heart work. I am afraid, and yet for you, rather glad, that you won't do this, for the reason it involves a lot of drudgery and wearisome work that will take up far more time than you can spare. You are now getting so busy and interested in other matters that you will not find the time. And yet it is a wonderful field it has opened up. These recent methods are generally assumed to be of interest in an academic sort of way but of no practical utility and recent writers of books refer to them in such a manner that this impression is encouraged placing the new methods in a sort of appendix. Now I find nothing so helpful in diagnosis, prognosis, and treatment as the application of the principles derived from them. I am just now in the throes of a book, where I attempt to bring them in the every day practical examination of patients. The undertaking involves [such a] breaking away from the well established methods of book making that I sometimes despair of doing justice to the subject. When you come to London I hope to be able to demonstrate the essentially practical nature of these new methods. I wish, however, it had been Burnley you were coming to, for I have here such a selection of cases that astonish all who visit me.

My reason for writing you so soon is that I want to know if you have kept the heart of that lad with mitral stenosis. I have now I think been able to establish that in mitral stenosis the rhythm of the heart starts at a node of tissues at the beginning of the a-v bundle. Some of the evidence is in a reprint I post with this. In certain rare cases there is a tendency for this rhythm to start for brief periods giving rise to attacks of paroxysmal tachycardia though the rate may not be greatly increased. I have had several of these cases and a very typical one died in an attack, but I mislaid the heart after noting the mitral stenosis. I feel fairly certain that if your patient's heart be microscopically examined there will be found an extension of the sclerotic process affecting the a-v bundle. Do you think you could get it examined?

It is curious your letter came when I was constructing a chapter on heart affections in neurotic people and had just finished the chapter on heart block which I take to be the cause in your man with the slow pulse. I have to go some forty miles tomorrow to see a very similar case. The cause I suspect is an extension of the sclerotic process cutting the bundle in two. When you come to London I will take you to Keith—one of the Lord's anointed—and he shall show you all these things.

I have had two most excellent articles from Hewlett, and I shall write him for a reprint of the articles you mention.

I had a wealthy lady with rheumatoid arthritis in her arm and she wanted another opinion so we motored down to Oxford and saw Osler. He was as chirpy as ever and told me you were going with him and Gibson to Vienna and he asked me to join the party. I fear it is one of those good things that will be denied to me.

We go to London on December first so if you are so good as to write to me, address me at 17 Bentinck St. W., London.

My wife bids me say she expects you to put up at that address, i.e., if you will be content with homely fare after the sybarite enjoyments of Oxford. I shall introduce you to these rare spirits—Cushny, Keith, Starling, Bayless, etc. You would do better work in London than with Krehl.

The book he was then writing, *Diseases of the Heart*, was published in the fall of 1908 and proved extraordinarily successful. He attributed to it the rapid growth of his practice in London after the first barren year. It was translated into German, French and Italian.

This letter reveals that at that time he was absorbed with the problem of the cause of the absolutely irregular pulse now known to be due to auricular fibrillation, and that he thought he had evidence that in this type of irregularity in mitral stenosis the rhythm begins in the auriculo-ventricular node; he therefore termed this rhythm "nodal rhythm." Although he then mistook its true nature, he recognized and differentiated this important group of the arrhythmias at a time when leading clinicians in Europe and America were ignorant of its existence. For years the pulse in those cases was described as intermittent and irregular, and no attempt was made to distinguish this arrhythmia from the irregularity of the pulse due to frequent extrasystoles. Mackenzie, on the other hand, stated in a paper published in 1908 that he had studied no less than six hundred cases of what is now called auricular fibrillation.

As early as 1898 he observed in a case of mitral stenosis that he had followed for six years that the auricular wave in the liver pulse, present in all previous tracings, disappeared, as did a "long murmur running up to and ending abruptly in the first sound, heard only at the apex." At the same time the pulse became irregular. He concluded that the patient had developed auricular paralysis. At the autopsy the auricles were greatly distended into thin-walled sacs "with a few strands of muscular fibres scattered over them." This explanation of the disappearance of the a wave in the venous pulse as due to paralysis was nearly correct, for the auricle, the seat of fibrillation, does not contract. The relation is certainly

close between the motion of a muscle that consists of a fine quiver and an actual paralysis. It is clear that Mackenzie's theory of nodal rhythm advanced in 1907 was much farther from the truth. He held to this theory until late in 1909, when Thomas Lewis showed that auricular fibrillation was the cause of the persistent irregularity. It was Mackenzie who stimulated Lewis to investigate the subject with the newly invented electrocardiograph. In the fourth edition of his textbook Mackenzie returned to his original designation, namely, paralysis of the auricle.

The next letter, dated January 31, 1908, was the first I received after he had moved to London. The book was nearly completed, and he was already in close touch with Cushny, who was investigating a subject of great interest to Mackenzie, namely, ventricular rhythm. This was the term applied to the contractions originating in the ventricles in cases of heart block.

Your letter relieved me. I had been told you were coming over in March and as I will have to go to Scotland until the end of March I am so afraid I might miss you. I am certain to be here all April, and will be free from the writing of my book which has engrossed all my energies for the last ten months and particularly so the two months I have been in London. I look forward to seeing you and will hope to make your visit here interesting and profitable. I regret, however, that I don't have any patients to show you, as there is absolutely no likelihood for my getting such a hospital appointment as I would care to accept, but I have one or two disciples and we may get the use of their cases.

I am glad your article for Osler is finished and I shall look forward to its perusal. I was interested in the fact that you had suggested His's bundle as the seat of irregularity. I remember a lecture of Clifford Allbutt in 1902, I think it was, in which he suggested "Gaskell's bridge" as the starting place. What a pity it was that you did not seek to carry out the suggestion by seeking for proof. The more searchers we get the nearer we will get to the truth. Though I got the idea about 1904, I am not quite convinced of its truth, for it has not been proven, and in my papers I make the suggestion boldly in order to stimulate others; and if they prove me wrong then I will rejoice at the discovery of the truth. In my book I do not take a strong standpoint, only suggest. I may say Professor Cushny has been able to produce the "ventricular rhythm" in dogs by aconitine and we are trying to get to its origin experimentally—but the difficulties are very great.

If you are really interested I think I will be able to start you well on your way during your stay with us. I am certain you will be pleased with the definite results you can get, especially when you have been engaged in the extremely difficult problem of metabolism.

I am glad you liked Starling. He is a delightful man as well as a great physiologist. You are right in regard to our physiologists. They are splendid men and so simple. Gaskell, for instance, is far ahead of any physiologist; even Engelmann, who has such a reputa-

tion, has only followed Gaskell's lead. It is the man who originates that is the great man, not the man who does the spade labor. Gaskell's work on the heart will place him next to Harvey in my opinion, and his work in the nervous system will give him a very high place in science.

I have been reading a lot of heart work lately, and I like the English better than the French and German. You will find that clinically and for practical recognition of conditions that writers like Broadbent are far ahead of any others. I have been reading Krehl, Romberg, and Hoffman and I am greatly disappointed in their clinical work. They are besides extremely badly informed of what other writers are doing and though they quote a lot of names you will find on deeper inquiry that the names are of little value and the reasons for their quotation . . . [illegible writing]. I don't want to flatter you but the papers you sent me were far more suggestive than any of these authors. They take such narrow views and expressed their views as if they were the only possible ones, and no more to be said. This "finality" particularly by French and German writers is one of the most amusing things I came across. I hope when you come here you will realize the strength of English clinicians.

In a paper published in 1904 I³ had said that a fatty change "in His' bridges, which transmits the contraction from auricle to ventricle, might impair the action of the heart while an equal fatty alteration elsewhere would not. Unfortunately no exact data are available. . . ." Mackenzie was right in criticizing me for not acting on the suggestion I put forward. I did not know at the time that, five years before my paper appeared, Wenckebach and His had independently suggested a lesion of the auriculoventricular bundle as the cause of heart block.

From July, 1906, onward I had under my care a Mr. Baker, who, because he lived near Boston, was referred to me for treatment with artificial "Nauheim baths," by my friend Dr. John H. Musser, whom he had consulted in Philadelphia. These were carbon dioxide baths of various strengths given at definite temperatures. Dr. Musser believed that the patient had beginning myocardial disease, and at that time it was generally held that carbon dioxide baths would strengthen the heart muscle. On September 1, 1907, Mr. Baker noticed slight difficulty in breathing, and his pulse rate, which had been normal, suddenly became slow. It was 38 to the minute when I examined him two days later, and subsequently I counted it as low as 28. After the bradycardia had continued for four months, the rate returned to normal. Because the patient was going to England in the spring of 1908, Dr. Musser agreed with me that it would be a good idea to have Dr. Mackenzie examine him. We thought he had had heart block, but definite proof was lacking. Mr. Baker was then fifty-three years old, the pulse rate

was normal and he was free from symptoms. I mention his name because Dr. Mackenzie referred to him repeatedly in his letters. He evidently never lost interest in his patients or forgot them. In the spring of 1924, sixteen years after he had examined Mr. Baker and less than a year before his own death, he wrote a note expressly "to hear how Mr. Baker had gone on."

I was present in Mackenzie's consulting room at 17 Bentinck Street when he examined Mr. Baker. Not much time was spent on the history or physical examination, and only a very few notes were made. The patient's pulse was regular and about 79 to the minute. Soon the ink-writing polygraph was brought out, and a continuous tracing of the radial and jugular pulse was made. Yards and yards of the paper ribbon passed through the machine and accumulated in wide loops on the floor. Mackenzie wanted to get the information he thought might be furnished by an extrasystole,

conductivity lead me to agree with your diagnosis of the condition when the pulse was slow — namely, that Mr. Baker had a transient heart block. On this point I will be able to speak with more certainty when I see the tracings. My diagnosis, — cardio-sclerosis, affecting the muscle wall, and extending to and partially destroying the a-v bundle.

The tracings, the arrival of which he was awaiting, had been made by Dr. George W. Norris, then Dr. Musser's assistant, at a time when Mr. Baker had bradycardia. On April 14 he wrote that the tracings had been received, and that they

confirm my diagnosis and render Mr. Baker's case one of great scientific interest, as few cases have such a good history of the change and confirms me in the view I have expressed in my book of the relationship of extra-systoles and "nodal rhythm" to heart block.

The prognosis is by no means bad, if he will be content with a crippled existence. If you should have to write Dr. Norris, tell him I think highly of the manner he has analyzed the tracings. There are not

FIGURE 1.

Tracing made by Dr. Mackenzie of a case of partial heart block.

but the pulse continued perfectly regular for many minutes. Finally after about twenty minutes, one extrasystole appeared on the tracing. Although the pulse was traced for some time longer, no other extrasystole was obtained. Figure 1 shows the polygraph tracing recorded at that time, April 1, 1908. The analysis made by Mackenzie was contained in a letter I received from him after I reached Heidelberg:

I promised to send you the tracing of Mr. Baker's auricular extra-systole.

The features brought out in the tracing are, a larger venous pulse than usual, and associated with it an increase in the heart's dullness, indicating a certain degree of dilatation. The tracing shows an increase in the a-c interval, slight but distinct. Normally at this rate of the heart's action the a-c interval rarely exceeds one fifth of a second, here the intervals (spaces A) are distinctly more than one fifth. The extra-systole is of auricular origin (a' in the jugular tracing). It is followed by a carotid wave, c', which I recognize as carotid because it is the same distance apart from the preceding wave, c, as the radial extra-systole, r', is apart from the preceding radial beat, r.

The a'-c' interval (space A') is greatly increased. This increase is rare in auricular extra-systole and is a further evidence of the impairment of the conduction of the a-v bundle. These undisputed evidences of delayed

six men in the United Kingdom that could have done it.

P. S. I have kept the original intact and copied in accurately the auricular extra-systole. If the American tracings are not of use to you I would like them, but you should keep them and publish a full account of this case in which case I shall let you have the original tracing we took together.

During the following years Mr. Baker continued to have recurrent attacks of complete heart block. Pulse tracings that I took during one attack were sent to Mackenzie with those of other cases of abnormal rhythm. On April 4, 1909, he wrote:

Your interpretation of the tracings is correct in each case. Note the difference in the a-c interval when there is heart block and when there is not (space A). I am sorry to hear of his recurrent attack. I shall look forward to the results of your endeavor to treat them. I expect a quiet God-fearing life will be best. . . . I got your letter yesterday and on the same evening I had an identical tracing of heart block sent me for my opinion from Sheffield. . . . If you can spare a bit of Baker's tracings I shall be glad to have it.

The statement that he looked forward to my endeavor to treat the attacks has a hidden meaning, which shows his tolerance to his friends who

held views regarding treatment with which he strongly disagreed. He knew that I believed that carbon dioxide baths strengthened the heart, and that I was employing them in the treatment of Mr. Baker. When Mackenzie was in Boston in 1906 I showed him the record of a patient with congestive heart failure who recovered after a course of such baths. He was quite right in failing to consider this favorable result as valuable evidence. I remember to this day his reply "Patients usually recover from their first attack of heart failure, no matter what treatment is employed." I pointed out to him that Krehl and Romberg, who were regarded as great authorities in heart disease, advocated treatment by carbon dioxide baths in their writings. He told me that I quoted Krehl and Romberg too much. I should make my own observations, do my own thinking and draw my own conclusions. I had worked under Krehl and doubtless was influenced by his teachings more than I should have been.

In his textbook, *Diseases of the Heart*, Mackenzie inserted a strong condemnation of the Nauheim baths. At that time they had a high reputation in England. He told me at the time he was writing his book that a professional friend who had read it in manuscript urged him to omit the criticism. This he refused to do. He had visited Nauheim, and did not condemn the method without reason. In the printed text he said, "Though I enter into this matter reluctantly, I conceive it nonetheless a duty to give my views on it, particularly as I am impressed with the injury done to individual patients through the unmerited reputation of the Nauheim baths among the medical profession." Mackenzie was right. The blast he directed against the Nauheim baths, natural and artificial, was effective, and nothing in their favor has supplanted the evidence he assembled against them over thirty years ago. Their use, in this country at least, lessened rapidly, and this was due in no small part, I believe, to Mackenzie's vigorous condemnation.

Before dismissing the case of Mr. Baker, an incident may be related that throws light on Mackenzie's attitude toward the financial side of medical practice. He was free from mercenary motives in moving to London. The character of many an able physician has been marred by an "itching palm." Not so Mackenzie. Mr. Baker was a wealthy manufacturer. He was, I think, the first patient referred to him from America, and he came on the recommendation of one of the leading physicians in the United States, Dr. John H. Musser. One day on the steamer going to England, Mr. Baker asked me how much Dr. Mackenzie

would probably charge him. I told him I did not know, but since Mackenzie was an international authority I thought he might rightly charge him any amount between \$75 and \$150. Mr. Baker seemed relieved and said that would be satisfactory. He added, "I feared he might stick me \$500." As I have already said, his total income the first year in London was only £114, hence, his receipts must have been very small up to the time I brought Mr. Baker to him. One morning after breakfast, I think on the day of the consultation, I asked Dr. Mackenzie how much he was going to charge my patient. "Three guineas is my fee." "If you do not charge Mr. Baker more than that," I replied, "it will make an unfavorable impression upon him. He will doubt whether I have brought him to a great heart specialist. He expects to pay you much more than that, and your opinion in his case is worth much more." It took much persuasion to induce Dr. Mackenzie to raise his fee. I think he charged Mr. Baker \$50 or \$60, I know it was less than the minimum figure I had mentioned. I did not know at the time how much he needed money. Lady Mackenzie told Mackenzie's biographer, Dr. R. MacNair Wilson,⁴ years later, "We were really and truly poor people." Their hospitality was unbounded. On two visits to London in 1908 I was their house guest all the time I was in the city. In the many talks I had with Mackenzie on those occasions he never expressed any fear that his London venture might end disastrously because of his failure to build up a practice. In fact, he never talked about financial matters.

After he had been in London a couple of months, Mackenzie had written me that there was "absolutely no likelihood for my getting such a hospital appointment as I would care to accept." But on May 24 he wrote "I have the offer, which I will probably accept, of having charge of wards in a hospital during August and September, beginning about August 7th. I wonder if you could delay your return to London until after August 7th, and come and work a short time with me in the wards. Turn this over in your mind and let me know." And on June 8 he wrote, "So far as I can see at present I shall get the wards about August 7th and if so we can have two or three days' discussion on the points that have arisen in your work in Heidelberg." He did not get the control of any wards, and this must have been a keen disappointment, but he never offered any explanation to me. He had learned, in Osler's words, "to consume his own smoke." I think he must have referred to the wards at the London Hospital under the care of

Henry Head, who was on a vacation at the time. We did visit the hospital one day, traveling to the east end of London on a bus. Mackenzie went to the basement of his home and smoked some tracing paper just before we started. He introduced himself to the sister in charge of the ward and said that Dr. Head had given him the privilege of examining the patients on the wards. We had a cool reception. I suspect Dr. Head had neglected to speak to the nurse. She simply bowed, and we began to walk from bed to bed until, without assistance, we found patients with heart disease. Mackenzie took out his polygraph and began to make tracings of the pulses of patients who had irregular rhythm. There was a house officer on the opposite side of the ward, but he did not offer to help us. In fact, he seemed to regard us with some suspicion. Finally the sight of the moving levers recording the radial and venous pulse aroused his curiosity. He crossed the ward and asked Mackenzie if that was a Hill-Barnard blood-pressure apparatus. "No," was the reply. "It is called a polygraph and was invented by a man named Mackenzie." Evidently disappointed, the young doctor walked away without another word. The polygraph and its inventor meant nothing to him. Only a few years later a new department for cardiac disease was created for Mackenzie in this same hospital. His nomination was made by no less a person than Lord Dawson of Penn, the King's physician.

In his earliest paper on the venous pulse, published in 1892, Mackenzie believed that the ventricular type, as he termed it, indicated dilatation of the right ventricle and tricuspid regurgitation. He held this view for years, in fact until he found that it was always associated with what he called "nodal rhythm," auricular fibrillation. In April, 1909, he wrote:

The variation in the jugular pulse in undoubted tricuspid regurgitation puzzles me and I can only dimly and unsatisfactorily speculate as to the cause. If you can settle the matter it will be a good piece of work. You can have no one better qualified to help you than Professor Porter. I think I did wrong to follow Frey's description of the auricular pressure. I think now that Porter is the truer. Some day I hope to apply his results to the venous pulse. I have already got some helpful tracings that way. Remember me kindly to him.

The next letter dates from the St. Andrews period and was written in April, 1924, only four months before ill health compelled him to retire to London. In spite of physical disability his mind turned incessantly to advancing knowledge and combating error.

I would strongly urge you to keep your instrument in good condition, because the polygraph is of far more use than the electrocardiograph. In the reprint upon cardiology which I sent you, you will see how much stress I am laying upon the output of the heart, and that it can only be registered by the sphygmograph, the electrocardiograph giving no information in regard to this important point. When you come to think of it, it is the capacity of the heart to supply the tissues with blood which we want to know, and that can only be done by ascertaining how the circulation is maintained in the body, and for this information we are dependent upon the patient's response to effort—the state of the pulse, and the presence or absence of signs of dropsy, etc. These essential matters are utterly beyond any instrument limited to the heart beat.

I am carrying the matter further than is represented in the reprint, for the small imperfect beats are those which give rise to heart failure, and it is by their suppression that digitalis proves so beneficial.

I see the old notion of operating on mitral stenosis is being revived. I wish surgeons would think of what the effect is of cutting scar tissue anywhere. It is only a small number of patients in whom the stenosis is a serious matter. The danger lies in the damage to the muscle, and almost to a certainty the cut in the scar tissue will unite again.

Another absurd piece of surgery has been carried out by the cutting of the sympathetic in angina pectoris. Of course, if a patient has gout in the big toe, the cutting of the afferent nerve will relieve the pain, but it will not cure the gout. If you think for a moment of the state of those hearts which are figured in my book on "angina" with the damaged coronary artery, and the great mass of damaged muscle, what on earth is the good of cutting the sympathetic? The pain may diminish, but its presence is actually beneficial, in that it provides a measure by which the patient can tell how much effort he should undertake. It is not the pain that is dangerous in angina pectoris. No person ever dies of pain. The pain only indicates the presence of some morbid state, and consequently, by relieving the pain you don't remove the morbid state. I have given the details of patients in my book to show that the pain or the angina itself is not necessarily a dangerous complaint, and if you read the history of some of these cases, you will see that people with angina can live as long as the average.

Partly as a result of Mackenzie's teaching, and partly as a result of personal observation and experience over a period of ten years, I was convinced that the best treatment for angina pectoris was prolonged bed rest. Knowing that Sir James, although afflicted with frequent attacks of angina, had been keeping at work, I wrote him of the excellent results I had obtained and urged him to seek the advice of his friend, Sir Clifford Allbutt, who was an ardent advocate of the bed-rest treatment and who had acquainted me with his success. He wrote that even in a "terrible case of angina pectoris, great relief if not cure" resulted from six months in bed. When Sir James Mackenzie received my letter he had only recently returned to

London and, as I learned later, was without medical care. It is always a hazardous matter to give unsought advice to a sick friend, especially if he happens to be the victim of a disease of which he is acknowledged to be the greatest living authority.

The following letter was written from London on September 10, 1924:

It is very good of you to write to me, and I appreciate very much your interest and your kindly suggestions. Your principle of treatment appeals to me. I have endeavored to follow it.

There is one danger, however, in a rule of thumb treatment in that it is apt to be used indiscriminately, and therefore to submit patients to treatment who do not need it, and fails to treat others who do not benefit by it but who are even made worse by it. In angina pectoris there are present morbid changes in the heart such as a narrowing of the coronary artery. This restricts the power of response of the ventricle so that effort produces pain. For a long time before pain arises there may have been persistent exhaustion which rest in bed does much to restore, but there are many circumstances other than effort which give rise to the pain. In my own case my first attack of pain was in 1908, and it arose in consequence of digestive indiscretion. I never had another attack of pain until two years ago, and then it was due to being chilled on a railway journey. For all these years I have known that the liability to pain was there, and ten years ago I used to be warned by the sense of constriction on going up hills, but invariably slowed down or stopped and the pain was never induced. During the war I led the most strenuous life that ever I had done, with out pain. Until eighteen months ago I played golf regularly, but on walking in the links, about a mile, I would have to stop every five hundred yards, caused by the constriction. Nevertheless I would play a round of golf without the slightest inconvenience.

The two great causes of pain in my case are exposure to cold, and mental excitement. When I avoid these I have no pain. I cannot walk now more than a few yards before I get the warning, but as I always stop I do not have severe pain from this cause.

All this means that my coronary arteries are slowly but surely becoming occluded.

I have written this in order that you may see the principles which we are trying to establish at St. Andrews particularly in regard to the response to effort in the circumstances that lead to such attacks as those of angina. Don't you think it a curious thing that notwithstanding the enormous amount of investigation that has been carried on that we are still as far from understanding the structures and processes concerned in the production of pain as were the pundits of the dark ages? Worse than that we don't even know what steps to take to get this knowledge. That is one of the problems I have been labouring at for forty years, and there is scarcely a physician who will take the trouble to find out what tissues, when stimulated, are capable of giving pain. In palpating the abdomen physicians and surgeons continually meet patients who complain of pain when pressure is made. No one, practically, takes the trouble to find out the structures which are being pressed upon which give rise to pain. Yet all physicians and surgeons resent the suggestion that they do not know how to palpate intelligently the abdomen.

I write you this because I know you like to face

problems. My wife and daughter join me in sending very best regards to you and your wife.

His last letter, dated November 18, 1924, was written only nine weeks before his death:

I was much interested in your letter and I am glad you propose attacking the problem of angina. Your suggestion of publishing the details of a series of cases is admirable. I have felt greatly the absence of such observations, for everyone who writes on the subject gives either particulars of a few cases which are quoted merely to support his own view or generalizations without proof. It was to provide a wide survey and to give the evidence for every statement that I cited so many cases.

But from your letter I see a danger in using them statistically. I had notes of 2000 cases. Half of them were too imperfect for use. Of the other 1000 I had full notes which enabled me to divide them into groups chiefly of three kinds, according to their gravity—or rather, their duration. There was a group where the complaint advanced slowly and the individual reached in advanced age. A second group where the disease progressed with greater rapidity and a third group where the progress was rapid and the patient died about middle life. The first group was by far the largest—700 or 800. The others much smaller. In the cases recorded in my book I give types of the groups independent of the number in a group. The largest of the groups were more of a type so that a few cases only were required. Of the others because of their gravity and individual character relatively more illustrative cases were given.

There was no clear dividing line between the groups. The grouping was done for convenience. Now if you take your series of cases and give their history and start comparing them with those I have given with which group will you select? It will be perfectly easy to select one of your cases which had, after an attack of angina pectoris, led an energetic life for ten and fifteen years and compare it with one of mine who died a few months after his attack and attribute the improvement of your case to your treatment, and the death in my case to the lack of your treatment. This is the fallacy of statistics.

I have many cases I put to bed and keep them there for weeks and months, but I discriminate. Look at the diseased hearts pictured in my book and ask yourself what conceivable treatment is likely to restore these hearts. Such conditions must have taken many years to develop. Discrimination can only come through recognizing the rate of the progress of the diseased condition and then can only be drawn by *estimating the response to effort*—i.e., by the amount of effort the patient can undertake without distress. Rate of pulse, blood pressure, etc., afford no help in the matter.

I get along quietly, taking as much exercise as I can without distress. I have only laid up one day, yet it is sixteen years since my first attack.

The clinical history and a careful and thorough study of Sir James Mackenzie's heart made at his request were published last year by Dr. David Waterston⁶ in the *British Heart Journal*. In the letter written four months before he died Mackenzie said, "All this means that my coronary

arteries are slowly but surely becoming occluded." The autopsy proved the correctness of this statement.

To my personal recollections and to this collection of letters I add in conclusion the fine appreciative sketch of this great man by the one whose name is closely united with his in the development of the clinical pathology of the heart. In a memorial tribute that appeared in the *British Medical Journal*, Sir Thomas Lewis⁶ said:

It was in 1908 and shortly after he migrated to London from his old home and practice at Burnley that I first came to know Mackenzie personally. While it was never my privilege to work under his supervision, yet he extended to me, though many years his junior, a friendship which soon became intimate and highly prized. I found in him during these years before the war, when we were in almost daily and personal communication, a man whole-heartedly devoted to the search for the knowledge of disease, and eager, most eager to impart his spirit and conceptions. He was an exceptionally vigorous and strong personality, intolerant of statements founded on tradition, trenchant and acute in criticism, rich in personal experience, combative in argument, but open nevertheless to conviction on all questions without reserve. He saw, as few or none of his day saw, where clinical knowledge ends and ignorance begins, and never hesitated to define the limits of his knowledge; and he was the first authority in clinical medicine on whose lips I frequently heard the words, "I don't know." To him diagnosis, the affixing of a temporary label, gave little

satisfaction; his patient still contained his problem or problems. Mackenzie's mind could not rest on the known, but turned incessantly at each and every hour of the day to the unknown, and in perceiving and defining the unknown he displayed a masterly power. To know Mackenzie intimately was to imbibe independency of thought; none could go to him seriously to discuss, and, surviving the brusque shocks of that first interview, return without a growing inspiration and stimulus. For he possessed a gift of stimulating others in unusual degree.

As a man he was hard headed and warm hearted, quick in temper and in sentiment, genial and hospitable, possessed of an invigorating, blunt humor. Schooled by long experience in the sensibilities, reservations, obstinacies and frailties of patients, he was an astute and shrewd physician, who rarely failed to inspire an unlimited and merited confidence.

This briefly of his practical work as I knew it; as a bedside investigator he ranks in my judgement as the first of his time; he has gone from us to hold a place in the history of British medicine by the side of Sydenham, Stokes, Graves, Addison and Bright, and he will live in memory as not the least of such men.

TRANSURETHRAL ELECTRORESECTION AS OPPOSED TO PROSTATECTOMY*

GEORGE GILBERT SMITH, M.D.†

BROOKLINE, MASSACHUSETTS

A DISCUSSION of the relative merits of two operations, entirely different in principle yet both designed to accomplish the same result, should be based on a consideration of the pathologic condition for which relief is sought. This is particularly true when obstruction at the bladder neck is the subject of discussion, for such obstruction may be caused by widely different processes.

Randall,¹ in a study based on the autopsy findings in 312 patients with prostatic obstruction, found 17 carcinomas, 57 fibrous bars, 31 glandular bars unaccompanied by lateral-lobe hyperplasia, and 207 cases in which hypertrophy of the lateral lobes existed alone or in combination with one of the preceding conditions.

A classification of the types of prostatic obstruction such as Randall has presented is of primary

importance in any discussion of transurethral resection as compared with prostatectomy. Obstructive conditions at the bladder neck are of two types: the enucleable and the nonenucleable. Carcinomas, fibrous bars and glandular bars unaccompanied by lateral-lobe enlargement, which were found in 33 per cent of Randall's series of bladder-neck obstructions, do not lend themselves readily to enucleation, as anyone knows who has attempted to remove them by this method.

Hypertrophied lateral lobes, on the other hand, may be cleanly and easily removed, through either suprapubic or perineal approach, by the simple process of breaking through the thin mucosa of the prostatic urethra at the point where it passes from the projecting lobe onto the roof of the urethra, and sweeping the finger along the line of cleavage between the hypertrophied mass and the prostatic capsule. This leaves a smooth, bowl-shaped cavity; its wall consists of compressed pros-

tatic tissue 2 or 3 mm thick, and at the upper and lower poles it narrows sharply to form the entrance and exit of the prostatic urethra (Fig 1)

That it might be possible to relieve bladder-neck obstruction of the fibrous type by transurethral methods has long been known, and Ribb¹²

FIGURE 1 Large Prostate with Easily Enucleable Lateral Lobes Lateral lobes partially enucleated (Reproduced from *Surgical Pathology of Prostatic Obstructions*¹ [p 59] by permission of the publisher)

has written a good historical review of the subject. One hundred years ago Mercier³ devised an instrument for the excision of bars at the vesical neck. Botuni⁴ in 1874 developed for this purpose an instrument resembling a lithotrite, the male blade of which was heated by a galvanic current. In 1909 Young⁵ introduced his "cold punch," which Caulk⁶ later modified by the addition of a cautery blade and a system of lenses.

Stern⁷ succeeded in applying high frequency current to the transurethral removal of bladder neck obstructions. His instrument was improved by Davis,⁸ who in 1931 reported 200 transurethral resections. The Stern-Davis resectoscope was superseded by the McCarthy⁹ resectoscope which has been the instrument most widely used in this country. A wire loop, set at right angle to the long axis of the instrument, is charged with a high-frequency current that enables the loop to cut through tissue and to coagulate as it cuts. The

operator moves the loop backward and forward by means of a lever, and can change the character of the electric current by means of a foot switch.

The Mayo Clinic has employed a different principle in transurethral resection, the obstructing tissue is removed with a cold punch, and the electric current is used only for coagulating bleeding points. This principle is sound, I believe, and in the early days of resection, when tissues cut by the McCarthy resectoscope were often considerably "overdone," it constituted a distinct advantage in favor of the cold punch. Recent developments in high frequency machines have given us a current that cuts with very little coagulation, whereas the Thompson¹⁰ resectoscope used at the Mayo Clinic

FIGURE 2 A Moderate-Sized Solitary Subcapsular Hypertrophy (Middle Lobe) Suitable for Transurethral Resection (Reproduced from *Surgical Pathology of Prostatic Obstructions*¹ [p 135] by permission of the publisher)

has so small a field of vision that the operator accustomed to the magnified view of the bladder neck given by McCarthy's Foroblique Lens finds the Thompson instrument almost impossible to use.

For the management of those types of bladder neck obstruction that are not readily enucleable, transurethral resection is admittedly the best method. One exception should be made; in certain early carcinomas, the total removal of prostate, vesicles and bladder neck as described by Young¹¹ offers a fair chance of cure, whereas re-

removal of the obstructing tissue by the resectoscope leaves behind that portion of the gland, the posterior lobe, in which from 75 to 80 per cent of prostatic cancers have their origin. Space does not permit the presentation of arguments in support of this rather dogmatic statement, but it is made on the basis of my experience with over 70 total perineal prostatectomies.

Although almost all urologists are in agreement as to the value of resection in nonnucleable obstructions, there is wide divergence of opinion as to its place in the removal of lateral-lobe hyper-

trophies. Most writers agree that small hypertrophies—let us say those not weighing over 20 gm.—may be sufficiently well removed by resection to promise a good result. When the larger hypertrophies are concerned, there is a parting of the ways. Some operators contend that practically any prostate can be resected, although two or more sessions may be necessary. Very few can remove over 50 gm. in an hour, and the leading advocates of resection warn against prolonging the operation beyond this time. Other operators believe that hypertrophies of more than 25 or 30 gm. can be removed more cleanly, more rapidly and even more safely by open operation.

In the early days of resection, surgeons were amazed to find that great relief of obstruction often

followed the removal of a few grams of tissue from the bladder neck. This was because the early cases were largely in the nonnucleable class. As larger prostates were attacked, it was learned that simply boring out a channel was not enough; incomplete removal of hypertrophied lobes often resulted in the extrusion into the urethral lumen of small adenomas. These sloughed, bled or obstructed urination. Recently leading resectionists have changed the name of this operation from "transurethral resection" to "transurethral prostatectomy"; they maintain that it is possible as well as essential to remove by transurethral methods the same amount of tissue that would be removed by enucleation.

I do not doubt that a few of the most skillful can approximate this objective, but the technical difficulties are many. The prostatic capsule is 2 or 3 mm. thick; to stop the process of resection at exactly the right depth all over the considerable area filled by good-sized hyperplastic lobes is practically impossible. If one leaves too much tissue, the operation may have to be repeated; if one cuts too deeply, the capsule is perforated and extravasation may result. Yet admittedly the operation is inadequate unless this almost impossible feat is accomplished. Actually, I believe, good clinical results are often obtained even if a considerable layer of hypertrophied tissue is left; this must be so, because we see many good results. The fact remains that the goal of this operation is practically unattainable.

Not so with open prostatectomy; as has been already pointed out, the removal of all the hyperplastic area is easily accomplished by following natural lines of cleavage. Why, then, is transurethral resection employed for those patients whose prostates are well suited for enucleation? The outstanding argument in favor of resection is its allegedly low mortality. In comparison with the mortality of suprapubic prostatectomy, this argument is well founded, but in comparison with that of perineal prostatectomy, it has no basis in fact. Johnson and Burns,¹² from collected series of statistics, found that in 4837 suprapubic operations the death rate was 12.4 per cent, whereas in 4370 perineal operations it was 3.3 per cent. Chetwood¹³ collected 27,000 cases of transurethral resection in which the mortality was 3.6 per cent.

It is true that in the hands of a very few specialists in resection the mortality is around 1 per cent, but against this we may set Bugbee's¹⁴ series of 233 suprapubic prostatectomies with a death rate of 0.8 per cent, and Young's record of 2800 perineal prostatectomies with a mortality of 2.8 per cent.

It is a significant fact that among those surgeons trained in perineal prostatectomy, not one, so far

as I know, has abandoned this method in favor of resection except in the nonenucleable type of obstruction.

The management of a condition that is so prevalent as the obstructing prostate cannot be concentrated in the hands of a few operators. Relief of prostatic obstruction will be attempted by practically all the eleven hundred members of the American Urological Association, and by numerous others less qualified for this type of surgery. Orr¹⁶ has shown that the mortality of transurethral resection has been much higher among those operators whose experience with resection has been limited to smaller series of cases.

My own mortality rate with resection versus perineal prostatectomy is definitely in favor of the latter. I have done resections on 200 patients. In the first 100 cases there were 6 deaths; 2 of these were in patients with cancer, 3 were in feeble or elderly persons who were had risks, and 1 was due to pulmonary embolus. In the last 100 resections there were 6 deaths attributable to the operation, as well as 1 death some weeks after resection from uremia and 1 from pyelonephritis. Three of the operative deaths were due to pulmonary emboli, 1 to upper respiratory infection, 1 to extravasation by the subtrigonal route and 1 to cardiovascular collapse. These figures are deplorable.

In the last 100 perineal prostatectomies that I have done, on ward as well as on private patients, and including several total prostatectomies, there were 2 deaths. One was that of a ward patient who entered the hospital because of cardiac decompensation and prostatic obstruction. His family physician insisted that he have his prostate removed, on the ground that neither cystostomy nor catheter life would be feasible. The patient died of a cardiac relapse four days after operation. I believe that resection would have been less dangerous, even though it had to be repeated, for the position required for perineal prostatectomy adds some load to the circulation. The other death was that of a man who bled more than usual and required transfusion. He made a good immediate recovery, but developed anuria and died twelve days after operation. Autopsy showed a tubular nephritis, considered by the pathologist to be the result of transfusion of improperly matched blood.

Another reason advanced for selecting the transurethral method has to do with the shorter stay in the hospital. One reads of patients discharged in less than a week after operation. In some clinics, this means that the patient is transferred to a nearby hotel, from which he is easily able to attend the outpatient department for daily observation. The possibility that secondary hemorrhage may oc-

cur about twelve days after resection makes it unwise to send these patients to their homes in other communities. I believe that the patient should be kept under close observation for at least ten days after operation; it is humiliating to have his own physician telephone to ask what he should do to stop the patient's bleeding. Second resections, which have to be done in 10 to 15 per cent of cases, lengthen the hospital stay.

Following perineal prostatectomy, patients stay in the hospital for two to four weeks. I seldom have one remain over three weeks unless some complication has occurred. Such complications almost always develop before the patient is discharged; the development of serious trouble after that time is rare.

It has been my experience that complete return to normal bladder function is slower in patients after resection than after open operation, although with increased familiarity with resection the results have been better. With cleaner and more complete removal of prostatic tissue, sepsis has been less troublesome. Urethral strictures develop after resection in a small number of patients. Nesbit,¹⁷ to avoid this, advises introducing the resectoscope through a perineal urethrotomy if the urethra is of small caliber.

Both perineal prostatectomy and transurethral resection may be followed by incontinence of urine. That which sometimes follows prostatectomy is almost sure to clear up within three months; I have had among my last 100 patients only 1 in whom control has not been entirely recovered. Although I have had no private cases of resection in which incontinence has persisted for more than six months, Davis¹⁸ tells us that the sale of penis clamps has increased from an average of 100 to 150 clamps for each year of the decade preceding 1928 to an estimated 1600 to 1700 for the year 1938. Since the period distinguished by this tenfold increase in the demand for clamps coincided with that in which transurethral resection developed, one might logically assume that incontinence has flourished *pari passu* with the spread of the latter operation.

Patients frequently ask whether transurethral resection gives as lasting results as does open operation. It is perhaps too soon to answer this question. Orr,¹⁶ from a study of 37 patients questioned or examined five or more years after resection, found that 33 had obtained both objective and subjective relief from their prostatic obstruction. It appears probable that if the resection is thorough, the relief will be as permanent as that after prostatectomy. After resection of a fibrous bar, lateral lobe hypertrophy may develop later, but

this cannot be considered an argument against resection.

These are, in brief, the advantages and disadvantages of transurethral resection as compared with open prostatectomy. I believe that for the surgeon who does an occasional prostatectomy, the suprapubic method is the safest. For the urologist who does a number of prostatectomies every year, it is well worth while to learn the perineal operation. The technic is really not difficult, although it is often so described. Perineal prostatectomy, and not suprapubic prostatectomy, is the true rival of transurethral resection.

No surgeon should attempt to do resections unless he has first-class equipment, which costs from eleven hundred dollars to twelve hundred dollars, and a well-trained hospital personnel who can carry out the details of postoperative care. To perform a resection well is far more difficult than to perform a good perineal or suprapubic prostatectomy.

Concerning my own attitude toward resection, I am definitely a selectionist. Approximately 45 per cent of the cases of prostatic obstruction that I see fall into the class for which resection seems the best method. These include the fibrous bars, carcinomas and small lateral-lobe and middle-lobe hypertrophies, and a few poor risks for whom resection seems the safest course. I find that I am much more satisfied if I remove the moderate and large hypertrophies by the perineal route. The operating time is less, complications are fewer, the mortality is lower. When I have finished, I know that the obstruction has been relieved and that I shall not have to tell the patient that he must make another trip to the operating room. There is definitely less mental stress for me, and a more complete and workmanlike job for the patient. Undoubtedly there are many urologists whose attitude toward resection is exactly opposite to mine.

Dr. George Brewster once said to me, "A surgeon should use that type of operation from which he can get the best results." This advice is essentially sound, and should be the criterion in the selection of a method for relieving prostatic obstruction.

DISCUSSION

DR. JOHN P. BOWLER, Hanover, New Hampshire: The crux of the situation is expressed in the conclusion of Dr. Smith's paper, in which he quotes Dr. Brewster to the effect that the best operation is that from which the surgeon is likely to get the best results; in other words, the point to be emphasized is that if the subject were approached from the point of view of the operator rather than of the operation, it would be clearly grasped. There is no doubt that transurethral resection has increased the armamentarium of the surgeon. In the past five or six years I have performed from a hundred and fifty to two hundred such resections, but I am still uncertain as to the value of this procedure. That mere statement is a condemnation of the operation—as well, perhaps, as of me.

The one advantage of transurethral section is that it has increased the operability of early cases with a small residuum—cases that previously have not been considered acceptable for open operation, but those that are relatively simple and in which there is slight risk.

One of the difficulties from the standpoint of practice is that this procedure has been presented to the general public as a minor operation, which is unfortunate. It has not been so in my cases, and certainly the postoperative care is far more detailed and important than that of the open operation.

I see no advantage in the Nesbit procedure. It is neither one thing nor the other, and the combination of urethrotomy and transurethral section seems to me unsound.

The type of operation is a matter for the operator to decide. Transurethral resection is not a minor procedure. It offers distinct advantages in the increased operability of early cases, and is of special value in malignant cases in which there is nothing to offer the patient but the palliation of obstruction. Most of us have not had so much experience as has Dr. Smith in the total perineal operation, so that we are compelled to resort to resection and x-ray treatment.

DR. J. DELLINGER BARNEY, Boston: Dr. Smith's paper is a splendid summary of his extremely safe and sane attitude toward the advantages and disadvantages of resection as opposed to open operation, whether perineal or suprapubic.

As happens in so many surgical fields, enthusiasm and lack of judgment have now given way to a temperate consideration of every case encountered. When resection first appeared, it was performed by everyone as a minor

and easy procedure that offered cure for all types of cases. It has now come to be realized that this operation is not always possible, and that even when it is, the results are often unsatisfactory. As a consequence, there is now being practiced a more scrupulous selection of cases for resection.

I now perform resections in 60 to 75 per cent of prostatic obstructions. This is much higher than my former percentage, because as one acquires more skill in the operation one is able to manage successfully cases that five or ten years previously one would not have dared to attempt.

Since resection must often be done in two stages, it subjects the patient to a great deal of unnecessary risk. The patient is frequently old and feeble, he must submit to a second anesthesia and go through a second convalescence, not to mention the mental and psychic excitement involved. This being so, the surgeon, unless he feels assured of success, should have recourse instead to open operation.

As to recurrence after resection, I have had only 1 case, an early one. The patient was a young man in good health, the resection was entirely successful, with no bladder symptoms and a clear urine. This condition lasted for five or six years, when obstruction developed, he finally had 10 ounces of residual urine. I performed a suprapubic operation, and found a large prostate that had probably grown after the resection, largely perhaps because I had not resected much tissue in the first place. I removed the prostate and the patient made an excellent recovery, he has been well ever since.

This operation, therefore, fills a distinct lack in being applicable to the type of prostate that Dr Smith has shown to be impossible or difficult to enucleate by a perineal operation. It is especially suitable for the cancerous prostates that used to be treated by suprapubic cystotomy, or by a fairly extensive perineal operation, which carried a high mortality and involved a great deal of unnecessary risk. The operation is also admirably adapted to old and feeble patients with small prostates. One can sometimes remove only a little prostatic tissue, yet obtain a perfectly good clinical result, and the patient, who will not live very long in any case, is made comfortable.

As time goes on and surgeons gain wider experience with this operation, they will select cases even more carefully, and will make sure that the procedure selected is the best one for the case in hand and involves the least risk to the patient.

DR FLETCHER H COLBY, Boston. I differ with Dr Smith in that I regard transurethral resection as the operation of choice for benign enlargement of the prostate or hypertrophy of the prostate whenever possible.

Ever since seeing my first prostatectomy, I have hoped for some better method of relieving urinary retention. Transurethral resection is perhaps not the answer, but it seems to come closer to it than open operation does.

As Dr Smith has said, it is necessary completely to remove all hypertrophied tissue to perform a satisfactory operation and obtain a good functional result. This requires skill and experience, but it can be done by transurethral resection as well as by open operation. Post mortem specimens removed after transurethral resection have shown the prostate to be as cleanly and adequately removed as would have been possible with any other method.

No good operation should be condemned because it is technically difficult. Resection offers the patient a shorter period of hospitalization, less postoperative pain and discomfort and at least as low a mortality and as good a functional result as open operation does.

Both perineal prostatectomy and transurethral resection are excellent operations, the latter is one of the outstanding contributions to urology. There is no reason why these two operations should conflict, since prostates that are of such size that they can be removed completely by resection are best so treated, and the others are best removed by perineal prostatectomy. The choice between the operations is really one of necessity, and depends on the operator's ability adequately to remove the prostate. The average hypertrophied prostate weighs about 45 gm, and this amount of tissue can be removed by transurethral resection in a reasonable length of time.

I have been able to determine the size of the enlarged prostate and its suitability for resection more accurately by cystourethrograms than by cystoscopic and rectal examination. Furthermore, their use spares the patient the discomfort and danger of cystoscopic examination.

Incontinence or rectal injury should never result from a properly performed transurethral resection. So far as this hazard of operation is concerned, a recent comparison of transurethral resection and perineal prostatectomy by two outstanding surgeons, Nesbit and Davis, showed that the functional result of the two operations was equal except for some incontinence after perineal prostatectomy.

In New England more has been said against than in favor of transurethral resection. I should like to see this operation as favorably considered here as elsewhere, so that patients would not think it necessary to go to other parts of the country to secure its advantages.

DR RICHARD F O'NEIL, Boston. I have heard many papers on this controversial subject but never one to compare with Dr Smith's in sequence, clearness and conviction. My colleagues have said about all that is possible to say on the subject, but I should like to add that we have been a little reluctant to carry out resection as freely in Boston as is done in other parts of the country, this policy is, in my opinion, a sound one.

DR SMITH (closing). I asked Dr Colby to discuss this paper because I knew that he represented a different point of view from mine. I suspect that we are not so very far apart, except in our psychologic reactions to resections. He likes to do them and I do not. I get much more satisfaction from an open operation where I can control every step by sight and touch, whereas Dr Colby probably, through his superior skill in the use of the instrument, feels more at home when he is working at the end of the resectoscope. I believe that if one has sufficient experience with these cases, one can become extremely skillful in transurethral resection, as has been demonstrated in certain well known clinics.

One of those present has said that total removal of the prostate by the resectoscope is possible. This statement was made at a medical meeting in Chicago, whereupon a number of surgeons declared that they had performed prostatectomies on patients on whom the speaker had performed resections. These remarks seemed to me rather cruel but they did show that the resectionist cannot be sure that he has removed all the obstructing tissue.

DISORDERS OF NUTRITIVE DEFICIENCY AND THEIR TREATMENT*

JAMES S. McLESTER, M.D.†

BIRMINGHAM, ALABAMA

THE composite picture that portrays the diseases of a people changes from time to time, just as do the sketches in a fashion magazine. True, a quarter of a century alters the lines in the first hardly as much as a single season alters the second, but the changes come just as surely. Thirty years ago the picture familiar to me in the Southern States was intensified by the high lights of typhoid fever, malaria and hookworm. In the next picture those lights were greatly subdued, and there appeared several ugly splotches made by pellagra. Today, the image is wholly different. As the pellagra splotches are being removed there is to be seen an entirely new coloration, all pervading, but in lighter tones, produced by a new group, the less outspoken forms of the deficiency diseases. Since this picture may confront you in New England, I should like to discuss some of its features.

It has well been said that few greater tragedies come to man than the emotional depression, the dulling of intellect and the loss of efficiency that accompany nutritive failure. This applies not alone to the well-characterized deficiency diseases such as outspoken beriberi, pellagra, scurvy and rickets, but with even greater force to these less clearly defined borderline states. They are of vastly more frequent occurrence.

My own interest in these disorders was first aroused by two experiences. In the effort to apply a modified form of the old Weir Mitchell rest cure to a group of patients who offered a large array of vague complaints, none of which could be related to any known disease, I was often gratified to find that the treatment was highly successful, but with almost equal frequency I was puzzled over the explanation of this success. In addition to rest and to psychotherapy of a sort, these so-called "neurasthenics" were given an abundance of food, in which milk and eggs bulked large, and, even though anorexia was a frequent complaint, it was insisted that the patient eat all that was offered him. The results were sometimes graphic. Nervous stability was restored, pains disappeared, vague discomforts were no longer complained of, and the patient's outlook

on life was often greatly improved. It finally became evident that it was the food, not the rest or the attempted psychotherapy, that cured the patient.

The other experience came when Dr. J. B. McLester reported that a significant number of patients coming to the Hillman Hospital with pellagra had been admitted the previous year with a diagnosis of neurasthenia. On further investigation it became apparent that before the skin lesions or other evidences of frank pellagra appear, there is often a preclinical state in which nervous instability and diarrhea are prominent features, and that in such cases the old designation pellagra *sine* pellagra is appropriate. We have made a diligent search for patients of this group, and a number have been found.

The deficiencies from which these patients suffer are almost always multiple. Indeed, frank pellagra, although apparently a disease entity, often presents evidence of more than one type of deficiency. Roughness and redness of the lips with inflamed fissures at the corners of the mouth may tell of riboflavin deficiency, or neuritis with edema may point to lack of thiamin and perhaps of protein. So difficult is it to determine precisely the nature of the deficiency from which the patient suffers that, with more seriousness than humor, there is occasionally recorded the diagnosis of "pellagra with a dash of beriberi." This is true not only of the outspoken disease, but also of preclinical pellagra.

The symptoms of preclinical pellagra include nervous instability, personality changes, mental depression, easy exhaustion, anorexia, vague digestive disorders and a tendency toward diarrhea. Often the tongue is red, or there may be merely a history of glossitis. On the other hand, there may be no symptoms other than anorexia and nervous instability. Any of these symptoms may be absent; instead of looseness of the bowels, for example, there may even be constipation. Untreated, the patient may the following spring develop outspoken pellagra, or without clearly defined symptoms he may for years remain merely in vague ill health. In either case adequate treatment will completely restore health.

Subclinical pellagra is not the only borderline form of nutritive failure encountered. There are

*Presented in part at the New England Postgraduate Assembly, Cambridge, Massachusetts, November 1, 1939.

†Professor of medicine, University of Alabama; physician-in-chief, Hillman Hospital.

many others, and in these sometimes one and sometimes another group of symptoms are seen. Digestive discomforts, with abdominal distention and anorexia, often predominate. Sometimes these are the only symptoms. The patients offering such complaints were formerly called neurasthenics, but it now appears that their disabilities are often genuine, being largely due to loss of muscle tone, which, like the neuritis of similar origin, is dependent on lack of vitamin B₁. Diarrhea sometimes dominates the clinical picture. Many years ago, we first began to see at the Hillman Hospital patients with achlorhydria whose only other evidence of disease was diarrhea. No doubt many of these had pernicious anemia, but not all. Some had early pellagra. The diarrhea of others was apparently nonspecific but was dependent nonetheless on nutritive deficiency. Patients of this last group usually recovered promptly when given an abundant diet, including liberal quantities of milk and eggs. Such patients continue to appear, and although even today their disorder cannot always be identified with any of the well-defined deficiency diseases, if they are given liver extract the diarrhea as a rule disappears.

Of a different type, perhaps, is the occasional patient with achlorhydria and an anemia of non-descript character who tells of one or two copious bowel movements each morning with nausea and, perhaps, profound exhaustion. During the rest of the day he feels well. Sometimes the tongue is red. In the sigmoidoscope the mucous membrane appears smooth and glistening, and in the fluoroscope the large bowel has a smooth, stringy appearance with loss of haustra. This is apparently a mild form of sprue, for large doses of liver extract given intramuscularly are always of benefit.

One of the commonest as well as the most distressing symptoms encountered in the borderline states is mental depression. Many deficiency disorders are accompanied by this symptom, but I have been particularly impressed by two groups of patients in whom mental depression predominates. In the one, nutritive failure is merely a contributing factor, in the other, it is apparently the underlying cause of the depression. As an example of the first group, I have seen a patient with typical manic depressive insanity of many years' duration greatly improved when the faulty dietary habits of a lifetime were corrected and nicotinic acid and thiamin given. Similar improvement has been seen in cases of so-called "involutional melancholia." Patients of the other group may present additional signs of nutritive failure, but as a rule nervous instability and emotional depression are the only evidences of ill health. I have seen pa-

tients of this type for whose depression no ready explanation could be found promptly regain their equilibrium and sense of well being when they were given intramuscular injections of liver extract. Other patients present a symptom complex identical with what is sometimes labeled toxic psychosis. They are confused, disturbed in speech and disorientated, and their gait is often unsteady. They are as a rule users of alcohol, though not necessarily to excess. When they are given thiamin and nicotinic acid, the psychosis, thick speech, and unsteady gait disappear.

Even the disabilities of old age are sometimes due in part to lack of nutritive essentials. An example of this was seen in the case of a charming elderly lady whose complaints of weakness, unsteadiness in gait and unwonted mental depression were at first regarded as the inevitable accompaniment of years. When it was discovered, however, that her tongue had the appearance of raw beef, although no fault could be found in her diet except its frugality, she was given large quantities of yeast, supplemented by thiamin and riboflavin. Immediately the tongue assumed a normal appearance and the patient's former sense of well being returned. This is not an uncommon experience. In such cases it seems fair to assume that the changes of advanced age have in some way interfered with the absorption and utilization of essential substances. I do not mean to suggest that adequacy in nutrition will prevent old age, far from it. I do make bold, however, to say that if the results of animal experiment can be applied to man, it can be assumed that long continued nutritive deficiency will hasten the onset of old age, and conversely that an optimal diet observed throughout the greater part of a person's life will postpone senility. What is of even greater interest, such a diet can be expected to prolong the person's period of usefulness.

Vitamin deficiency is not the only cause of nutritive failure. Deficiency disorders are produced just as effectively, though not always in so graphic a manner, by lack of proteins and of minerals. Witness the endemic edema that is due in part to protein deficiency, as is the edema sometimes seen in pellagra. Of similar nature is the puffiness of the ankles exhibited by patients convalescing from a long illness. Even the so-called "toxemia of pregnancy" described by Strauss is apparently due to lack of protein. Here again, if the results of experiments on animals can be applied to man, it may be assumed that lack of protein in the diet will lead to easy exhaustion, loss of stamina and other disabilities, this accords with clinical experience.

Lack of iron is also a potent cause of trouble. I

have been impressed by the frequency of iron-deficiency anemias. It has repeatedly been observed that this type of anemia occurs oftenest in women in the late teens or about the time of the menopause. These are frequently apparently healthy girls and young women who complain only of easy exhaustion, and not always of that. This disease seems to me to be identical with the chlorosis described here and in England forty years ago, but I am under the impression that we see it in the South today more frequently than it is seen in New England. The combined demands of growth and menstruation, and in addition oftentimes a freaky appetite, with a deficient diet are probable causative factors. Another form of iron-deficiency anemia is that described as the idiopathic anemia of middle-aged women with achlorhydria. Many of these patients are chronic invalids who live on a diet deficient in iron. Menorrhagia and bleeding hemorrhoids may also be causative factors. There is reason for believing that in the first group, and possibly in the second group also, difficulties of absorption play an important role.

For the prevention of nutritive failure, a reasonably liberal, well-balanced diet is as a rule sufficient; it is well to emphasize, too, that for this purpose vitamins and minerals should be obtained, not from the druggist, but from the grocer and the dairyman. This is not true, however, in every case, for there are many conditions in which nutritive needs are greatly increased, and the food, therefore, should be fortified with more concentrated substances. These conditions may be physiologic, as in increased exercise and in pregnancy and lactation. At other times the increased demand may be due to illness, as in infectious diseases, hyperthyroidism and many forms of chronic illness. In addition, the possibility of inadequate absorption must be considered. The absence of bile from the intestinal tract, achlorhydria, frequent diarrhea or a history of alcoholism should provide a warning that nutritive substances taken by mouth may not be adequately absorbed. In such cases greatly increased amounts of these substances should be given, or they should be administered parenterally.

The distorted anatomic relations and consequent disturbances of function that occasionally follow a short-circuiting or other operation on the bowel may lead to nutritional failure no matter how abundant the diet. Such a fault can rarely be corrected, but I recently saw this accomplished in a very gratifying manner by means of a second operation. In the effort to prevent deficiency disease, therefore, particularly after a febrile illness or in the presence of gastrointestinal derangement, the

diet should be considered from two viewpoints, first in the light of the person's nutritive needs, and secondly in regard to his ability adequately to absorb and utilize all essential substances.

Once, however, the deficiency becomes manifest, the picture changes and the need grows vastly more urgent. Treatment under these circumstances should be governed by three principles, which are as follows.

First, the patient can no longer depend solely on the grocer and the dairyman. Recourse must be had also to the pharmacist, and the missing substances be secured in concentrated form.

Secondly, because the deficiencies under discussion are seldom single, more than one vitamin or other essential substance must as a rule be given. Pellagra, for example, cannot always be cured with nicotinic acid alone; thiamin and riboflavin also are often needed, as well as proteins of good quality. A like condition obtains in many other states of nutritive failure, and for this reason two substances have come into use that are especially suitable, yeast and liver extract. The value of the latter when given intramuscularly has been demonstrated in a number of nutritive disorders, both outspoken and borderline. This, no doubt, is because the liver as the "commissariat" of the body elaborates and stores a number of essential substances. Extracts made from this organ can provide not only the antianemic principle but also other necessary material, and such preparations should not, therefore, be too highly concentrated. Even in such a clear-cut deficiency disease as pernicious anemia the patient often gets a greater "lift" and his sense of well-being reaches a higher plane if he is given the liver extract that carries the broader fractions.

Thirdly, the needed substances must be given in relatively enormous amounts. Before the nicotinic-acid era, for example, it was known at the Hillman Hospital that the daily dose of brewer's yeast that could with maximum benefit be given pellagrins was 180 to 270 gm. (a half pound!). Although 1 mg. of thiamin is regarded as the maintenance dose, it has been found in deficiency states that 20 to 50 mg. daily must be given before clinical improvement is seen, and cases of nerve injury have been reported in which 100 mg. of this vitamin daily were required. The same is true of vitamin C. Whereas 40 to 60 mg. has been estimated as the optimal intake, deficiency states have been reported in which ten to twenty-five times this amount was necessary. Likewise, in the use of liver extract I have found that vastly better results can be obtained if very large amounts

are used; massive doses sometimes bring excellent results when small doses have accomplished nothing. It is difficult to understand the magnitude of this need unless it be that it is due in part to the

necessity for replenishing exhausted stores. The physician who would treat deficiency diseases cannot afford to be timid.

MEDICAL PROGRESS

CLINICAL BLOOD CHEMISTRY IN GENERAL PRACTICE*

WILLIAM T. SALTER, M.D.†

BOSTON

THE extensive use of blood chemistry in clinical medicine was established largely through the efforts of the late Professor Otto Folin,¹ within the memory of the present generation of active practitioners. The value of such procedures to confirm bedside impressions and to follow quantitatively the progress of disease is now unquestioned. Two general abuses, however, have arisen: the abandonment of sound clinical observation and clear thinking in favor of laboratory reports, and the misinterpretation of such data through ignorance of their limitations and of the several factors that together yield a given physiologic concentration. These abuses will disappear only when physicians become better acquainted with the intricacies of human physiology.

To call attention to the possible pitfalls that confront the interpreter of chemical data, this synopsis of common laboratory tests has been formulated. It should be read with the mental reservation that, owing to various physiologic complexities and analytical complications, the statements made below are not over 80 per cent correct.

The constituents of the blood that are commonly used in clinical medicine may be classified arbitrarily as follows: plasma proteins; nonprotein nitrogenous compounds; sugar; lipoids; pigments; calcium and phosphate; bases (cations); acids (anions); and regulators (vitamins, enzymes and hormones). In the summary that follows, only the commonest examples of each of these are cited.

Whole blood versus serum or plasma. Because blood is a two-phase system of cells and plasma, determinations of concentrations in whole blood record necessarily the average of two values, that is, the concentration in the cells and the concentration in the plasma. In general, plasma or serum values are preferable, because they reflect

more directly the true *milieu interne*. Moreover, differential permeability complicates the problem. Thus human red blood cells probably contain no calcium; if a calcium estimation were performed on whole blood, therefore, the answer would record the net effect of a 45 per cent fraction (cells) containing no calcium, plus a 55 per cent fraction (plasma) containing 10 mg. per 100 cc. of calcium. Thus the whole blood calcium would be 5.5 mg., but it would vary with the hematocrit reading.

The differences are even more confusing when chloride or carbon dioxide is investigated, because these substances may shift from plasma to cells, depending on circumstances. Moreover, the variation in the normal range may lead to serious misunderstandings. For example, a recent diagnosis of Addison's disease was falsely made because a *whole-blood* value for chloride of 80 milliequiv. per liter (normal) was reported to a clinician who was accustomed to think in terms of the normal *plasma* value of 108 milliequiv. Similarly, a *plasma* carbon dioxide combining capacity of 70 vol. per cent was misinterpreted as evidence of alkalosis by a clinician who was accustomed to think in terms of the normal *whole-blood* value of 48 vol.

With rare exceptions, it is advisable to avoid the use of whole blood, by employing plasma for all determinations except inorganic electrolytes, for which serum may be used. At the present time, however, whole blood is used for many purposes, so that this synopsis will describe values for it in those cases in which it is commonly employed.

PLASMA PROTEINS

Plasma proteins are ordinarily determined by some modification of the Kjeldahl procedure. After oxidation and digestion the ammonia nitrogen may be determined either by alkalimetric titration or colorimetrically after nesslerization. Reliable methods are given by Folin.¹ In my² progress report for last year, modern revisions of protein frac-

†Assistant professor of medicine, Harvard Medical School; associate physician, Thorndike Memorial Laboratory; junior visiting physician, Boston City Hospital.

tiation were discussed. The fractions described here, however, represent the old-fashioned partitions still in common use.

Normal values usually range from 6.5 to 7.5 gm. per 100 cc. Rarely, values of 6.3 to 8.0 gm. are found under physiologic circumstances. The protein may be subdivided as follows: albumin, the value for which is usually between 3.8 and 4.4 gm.; and globulin, the value for which is usually 2.2 to 3.4 gm. The value for fibrinogen is usually under 0.6 gm. and is ordinarily included in the globulin fraction. The albumin-globulin (A:G) ratio, therefore, is usually between 1.4 and 2.2.

Low values for total protein are encountered in parenchymatous Bright's disease (the so-called "nephrotic" syndrome), in malnutrition and in infections. In *edema* the critical average values that herald the onset are for total protein 5.0 to 5.5 gm. per 100 cc., and for albumin 2.5 gm.

High values are commonly found in the marked dehydration that accompanies vomiting and diarrhea. Thus in cholera the total protein may reach over 11 gm. per 100 cc. Values over 12 gm. are not uncommon in multiple myeloma. In lymphogranuloma inguinale some elevation of protein is also common. The globulin fraction tends to be high in hepatic inflammation but usually falls after extensive liver damage. Among the infections, kala-azar commonly produces high globulin values.

NONPROTEIN NITROGENOUS COMPOUNDS

Blood Urea Nitrogen

The value for blood urea nitrogen may be determined gasometrically by measurement of the nitrogen evolved after treatment with hypobromite. It is also very conveniently estimated by the determination of ammonia after treatment with the enzyme, urease. Reliable methods are given by Peters and Van Slyke.³

Normal values are usually between 9 and 14 mg. per 100 cc. Rarely, values of between 5 and 23 mg. are found under physiologic circumstances. This variability is usually due to changes in normal nitrogen metabolism. For example, Priestley and Hindmarsh¹ found that when the urinary nitrogen reached 11.2 gm. per twenty-four hours the blood urea nitrogen was 11.3 mg. per 100 cc.

Low values are frequently found after diuresis because urea is swept out with body water. The values tend to be low in pregnancy and in acute yellow atrophy of the liver. Because a high-carbohydrate diet spares protein metabolism, the

normal range may drop 40 per cent when carbohydrate is forced.

High values are found in dehydration, in primary renal insufficiency and in renal insufficiency due to congestive heart failure.

Special tests. Two clinical function tests involve the determination of blood urea nitrogen. The urea-clearance test of Van Slyke⁵ relates the urinary urea to the blood urea by determining the volume of blood theoretically cleared of urea in one minute. The Mosenthal index⁶ is the ratio of blood-urea nitrogen to total nonprotein nitrogen multiplied by 100. The upper limit of normal is 44. Values above 80 suggest strongly Bright's disease and impending uremia. A normal ratio with high total nonprotein nitrogen suggests that primary renal insufficiency is not present.

Blood Nonprotein Nitrogen (Total)

After precipitation of blood proteins, the total nitrogen in the filtrate is estimated after Kjeldahl's digestion. The ammonia so formed is commonly determined colorimetrically after nesslerization. Reliable methods are given by Folin.¹

Normal values usually range between 25 and 35 mg. per 100 cc., rarely between 25 and 40 mg. Occasionally, a normal person on a high-protein diet may show 45 mg. The total nonprotein nitrogen represents the sum of nitrogen moieties contributed by urea, aminoacids, uric acid, creatine, creatinine and the undetermined nitrogenous material in the blood filtrate. The nonprotein nitrogen concentration is higher in the corpuscles. In the plasma, it is ordinarily only 18 to 30 mg. per 100 cc., that is, approximately twice the blood urea nitrogen. The discrepancy between corpuscles and plasma is due largely to nitrogenous material of unknown composition; consequently, plasma determinations are much to be preferred. In general, considerable variations of nonprotein nitrogen are caused by alterations in urea nitrogen, in the undetermined nitrogen fraction, or in both. Blood nonprotein nitrogen reflects the balance between protein catabolism and urinary elimination. Consequently, there are considerable diurnal variations that bespeak the necessity of determining fasting values. Retention of water or diuresis will also change the nonprotein nitrogen.

Low values are found in starvation, in cachexia and to a certain extent in pregnancy. Unlike blood urea nitrogen, the total nonprotein nitrogen is ordinarily not affected in moderate hepatic disturbance.

High values are found in the characteristic azote-

nia of nephritis, in which values ranging from 100 to over 200 mg. per 100 cc. are common in the terminal stages or during acute exacerbations. Poisoning from mercury and uranium, as well as that from certain drugs, has much the same effect. One may find a high nonprotein nitrogen in dehydration such as that associated with heat cramps, after severe burns, including x-ray necrosis, in the crises of hyperthyroidism, in hyperparathyroidism of marked degree, in advanced hepatic cirrhosis and in gastrointestinal obstruction associated with repeated vomiting or after prolonged severe diarrhea, as in cholera. Even such common disturbances as chronic passive congestion, surgical shock, severe fevers, acute infections, diabetic coma and, possibly, uncomplicated gout lead to some elevation. Lack of salt, particularly in the crises of Addison's disease, is associated with azotemia. Azotemia also accompanies the hepatorenal death found in Weil's disease.

Blood Uric Acid

The value for blood uric acid is ordinarily determined colorimetrically. A convenient method is that of Folin.⁷ Uncertainty still exists as to how uric acid is distributed between cells and plasma, and for this reason it is probably much better to use serum.⁸

Normal values are, for blood, 2.0 to 4.5 mg. per 100 cc., and for serum 3.0 to 5.0 mg. These values vary considerably in different laboratories, according to the technic used. In general, any single value of 6 mg. or above should be repeated, even though there is no clinical indication of gout. *Normal* values are affected somewhat by meals, especially those high in fats and nucleins.

Low values are not striking, but tend to occur after such medication as thyroid, cinchophen or colchicine and after diuresis induced by calcium chloride.

High values may be produced by fasting, especially in children, in whom a four-day fast may cause an elevation up to 10 or even 12 mg. per 100 cc. On the other hand, this condition may be relieved by the feeding of carbohydrate, protein or aminoacids. The feeding of thymus (true sweetbread) may cause a moderate rise. In gout (podagra), elevations in serum uric acid concentration from 5 to 11 mg. per 100 cc. occur in the majority of cases if repeated determinations are made at appropriate critical times.⁸ Moderate elevations are common in leukemia, in advanced chronic nephritis and in polycythemia. Pneumonia may cause a temporary rise, and even severe exercise may increase the value about 1 mg. per 100 cc.

Blood Creatinine

The value for blood creatinine is commonly determined by the colorimetric method of Jaffe, which involves the use of alkaline picrate. A reliable modified method is that of Danielson.⁹ There is an academic dispute whether *in vivo* creatinine exists as such or in the form of a chemical precursor. This material is distributed equally between cells and plasma. Its concentration is more constant than that of any other nitrogenous component of the blood. It is essentially unaffected by age, diet, exercise or pregnancy.

Normal values range from 1.0 to 1.8 mg. per 100 cc.

High values, up to 5.0 mg. per 100 cc., are common in chronic nephritis. Indeed, most clinical values over 2.5 mg. are due to nephritis. Above 10 mg. the prognosis is ordinarily very poor, and a value approaching 18 mg. implies imminent death. In urologic conditions producing obstruction low in the urinary tract, the creatinine tends to be but slightly elevated, even when the blood urea nitrogen is high. This point is of diagnostic interest in prostatism, urethral stricture and cancer of the bladder.

SUGAR

Blood Glucose

The value for blood glucose is ordinarily determined colorimetrically by one of the two Folin methods involving either an alkaline copper reduction¹ or the ferricyanide reagent.¹⁰ Of course, many other reliable reagents and methods have been described, such as the Somogyi¹¹ or Shaffer-Hartmann¹² titration methods. The corpuscles contain much reducing substance that is not glucose. For this reason the use of unclotted blood was introduced by Folin.¹³ Probably fresh plasma or serum is preferable from a chemical standpoint. In general, blood glucose tends to be destroyed rapidly unless careful measures are taken to preserve it.

Normal values of about 70 to 100 mg. per 100 cc., fasting, are obtained by the methods mentioned. Over 130 mg. is probably abnormal. For whole blood, between 20 and 30 mg. of the reducing substance is probably not glucose. In the cells as much as 41 to 51 mg. of false reducing value is found, whereas only 7 to 13 mg. is present in plasma.

Low values occur in starvation, in pituitary hypofunction, in exhaustion, for example, during a marathon race, and in Addison's disease. In severe liver necrosis due to phosphorus or chloroform poi-

soning and in acute yellow atrophy of the liver, severe hypoglycemia may cause fatal convulsions. In tumor of the pancreas, or hyperfunction such as may follow the assimilation of glucose, marked reduction of blood sugar may occur.

High values are found in excitement, fear, cold and asphyxia (especially in carbon monoxide poisoning) and after brain injury. These conditions represent reactions of the sympathetic nervous system, as described by Bernard and also by Cannon.¹⁴ Hyperglycemia after meals is common in hyperthyroidism and may simulate closely true diabetes mellitus. Even in normal people, it is said that so-called "alimentary hyperglycemia" may lead to glycosuria. A variety of nondescript disturbances may cause intermittent glycosuria. In the dehydration of children and in eclampsia these may be accompanied by temporary hyperglycemia, but in uncomplicated renal injury the blood sugar is usually normal. The differentiation of various clinical types of glycosuria is well discussed by Joslin and his associates¹⁵ in the well-known monograph on diabetes mellitus.

Glucose-tolerance curves. This procedure has assumed increasing importance since the recognition of the role of the pituitary gland in diabetes, as described by Houssay.¹⁶ The simultaneous administration of insulin is now used as a special form of differential functional test, as discussed by Himsworth.¹⁷ It should be remembered that venous blood tends to be lower than arterial blood in the normal postabsorptive patient, whereas the reverse may be true in diabetes.

LIPIDS

Blood Cholesterol

The value for blood cholesterol is usually determined colorimetrically by the acetic anhydride reagent,¹⁸ but it is widely recognized that this method includes other substances. The extent of the error depends on the details of the manipulation involved, so that the normal range varies a great deal with local conditions. For research purposes, precipitation by digitonin¹⁹ is sometimes preferred, despite the high cost of the reagent. The total cholesterol may be divided into two portions, that is, the free and the esterified. Cells and plasma contain the same concentration of total cholesterol, but in the fasting state the red cells contain practically no cholesterol ester. In the normal plasma, free and esterified cholesterol are present in constant and nearly equal proportions.

Normal values in many laboratories range from 140 to 170 mg. per 100 cc., rarely from 100 to 230 mg., for total cholesterol.

Low values are found in prolonged starvation,

in cachexia, in scurvy, in severe infections and in certain anemias. In infancy, values as low as 50 mg. per 100 cc. are not uncommon. In hyperthyroidism, cholesterol tends to fall as the basal metabolism rises, but there is no reliable standard by which to evaluate a single determination in the individual patient.

High values, such as 300 mg. per 100 cc. or over, are found in pregnancy, myxedema and the so-called "nephrotic syndrome." Cholesterol may be increased in diabetes, but this is not invariable. After a meal there is usually a slight rise in total cholesterol, and after the ingestion of meat this rise may be prolonged. In liver disease, especially when icterus is present, cholesterol is elevated. The ratio of esters to free cholesterol is characteristically low in parenchymatous disease of the liver.

PIGMENTS

Plasma Bilirubin

The value for this pigment is usually determined by van den Bergh's colorimetric reagent. A convenient modification is that of Rhamy and Adams.²⁰

Normal values range from 0.25 to 0.6 mg. per 100 cc., corresponding to an icteric index of less than 8. One van den Bergh unit equals 0.5 mg. per cent bilirubin. It should be noticed that the quantitative van den Bergh procedure does not reflect the qualitative type of jaundice.

High values are now rarely found in pernicious anemia, although a moderate elevation was formerly common, that is, 1 to 2 mg. per 100 cc. or an icteric index of 20 to 25. Somewhat higher values often occur in hepatic cirrhosis. In hemolytic anemia the increase in bilirubin varies with the disease. In obstructive jaundice or in acute yellow atrophy extremely high values are found, for example, over 40 mg. per 100 cc., corresponding to an icteric index well over 100. As a rough approximation, skin pigmentation occurs at 4 van den Bergh units, equaling 2 mg. per 100 cc. or an icteric index of 20.

The qualitative van den Bergh test is now thought by many investigators to be of dubious value in most cases. It rests on the principle that normal blood plasma contains colloidal bilirubin, whereas normal bile contains the pigment after detachment from its colloid carrier. The qualitative test should not be confused with the quantitative procedure used to determine total bilirubin. Characteristic findings in different types of jaundice are summarized in Table 1. It should be mentioned that obstruction due to stone in the common bile duct is rarely complete when subjected to such quantitative evaluation. On the other hand, cancerous obstruction is frequently complete.

CALCIUM AND PHOSPHORUS

Serum Calcium

The value for serum calcium is usually determined by titration (with permanganate or with acid) after precipitation as calcium oxalate. Obviously, oxalated plasma cannot be used for this determination. A reliable method is that of Fiske and Logan.¹¹

Normal values range from 9 to 11 mg per 100 cc, that is, a concentration of 5 milliequiv per liter (25 millimolar). Ordinarily, 3 to 5 mg per 100 cc of this amount is bound to protein. Other things being equal, calcium falls as inorganic phosphate rises, and conversely, calcium rises with in-

vitaminosis D may in extreme cases push the level up to 40 mg for short periods, apparently without marked deleterious effect. The synopsis in Table 2 is intended simply to give a rough idea of the combined blood findings in tetany. Exceptions to the findings recorded in the table are given by Peters and Van Slyke.⁸

In parathyroid disease the usual or characteristic combination of findings is as follows. In hypoparathyroidism calcium is low, phosphate is increased, calcium excretion and phosphate excretion are both diminished, serum phosphatase (see below) is normal, and tetany is present. In hyperparathyroidism, on the other hand, calcium is elevated, phosphate is diminished, both calcium and

*Except in acholic stool per day

†Data represent 24 hour periods

crease of plasma protein. These two trends should be considered in evaluating the virtual normal in any given case. Mathematically, they may be expressed more precisely by the following equations:

$$\begin{aligned} \text{At pH 7.4, calcium (mg per 100 cc)} &= 0.556 \text{ protein (gm per 100 cc)} + 6 \text{ or, for adults, calcium} \\ \text{(mg per 100 cc)} &= 0.556 \text{ protein (gm per 100 cc)} \\ &- 0.255 \text{ phosphorus (mg per 100 cc)} + 7 \end{aligned}$$

This last equation refers to inorganic phosphate, expressed in terms of its inherent phosphorus.²²

Low values, for example, 4 mg per 100 cc, are found in severe hypoparathyroidism. In nephritis the calcium drops as phosphate retention ensues or when malnutrition produces low plasma protein. In Gee's steatorrhea (adult celiac disease) excessive loss of calcium soaps by the bowel may reduce the serum calcium to well below 7 mg. Two types of osteomalacia are recognized. In the first, calcium is little reduced but phosphate is subnormal, in the second, calcium is low and phosphate is normal to slightly increased. The latter type occurs much more commonly. Ordinarily, clinical tetany is likely to occur with values below 7 mg per 100 cc and is imminent below 5 mg.

High values may occur secondary to increased plasma protein, as in multiple myeloma. In hyperparathyroidism, increases are found up to a critical level of 20 mg per 100 cc. Artificial hyper-

phosphate excretion tend to be increased, serum phosphatase is often increased, and there is neuromuscular hypotonia.

Normal values for serum calcium are the rule in Paget's disease (osteitis deformans) and in hy-

TABLE 2 *Blood Findings in Tetany*

TYPE OF TETANY	SERUM CALCIUM	BLOOD BICARBONATE	PLASMA pH	SERUM PHOSPHATE AS P

perthyroidism. This is true in spite of the abnormally high calcium elimination during the active phases of each of these disturbances.

Serum Phosphate

The value for the phosphate ion (H_2PO_4^-) is ordinarily determined colorimetrically with a phosphomolybdate reagent; the result is expressed in terms of the inherent phosphorus. A convenient method is that of Fiske and Subbarow.²³ The cell content is in dispute.

Normal values for adults' serum range from 2 to 5 mg per 100 cc, for infants' serum, from 4 to 7 mg. Although inorganic phosphate is the type of phosphorus compound ordinarily referred to in the clinical literature, occasional reference will also be

found to acid-soluble phosphorus, for which normal ranges are as follows: in adults the cells contain 44 to 82 mg. per 100 cc. but the serum only 2.5 to 5.5 mg.; in infants the cells contain 43 to 70 mg., and the serum 4 to 8 mg. This acid-soluble phosphorus fraction exists in addition to the inorganic phosphate commonly referred to. In all cases the values refer to inherent phosphorus.

Low values for inorganic phosphate are found in the common variety of rickets and probably in the late rise characteristic of advanced, terminal hyperparathyroidism. Of the two known types of osteomalacia, that with low serum phosphate is found occasionally. Forced breathing may reduce inorganic phosphate to 1 mg. per 100 cc. of phosphorus. Likewise, insulin and adrenaline cause a fall.

High values are found in hypoparathyroidism, in acidosis induced by carbon dioxide and after the administration of pituitrin. In chronic nephritis inorganic phosphate retention has important prognostic significance. At 8 mg. per 100 cc. the condition becomes critical, and at 20 mg. death is to be expected.

Because phosphate is intimately connected with the chemistry of carbohydrates, fluctuations in carbohydrate metabolism frequently alter the concentration of serum phosphate. It is interesting that despite the marked clinical correlation of high plasma phosphate with low serum calcium, the onset of tetany is not directly related to the phosphate except through pH and calcium. Indeed, there is scientific evidence that the local concentration of carbon dioxide in the tissues, not the calcium or the reaction, is the final precipitating factor in tetany.²⁴

BASES

Serum Total Base

The serum total base represents the sum of the extracellular blood bases: sodium, potassium, magnesium and calcium.²⁵ It is often determined electrolytically, by the method of Consolazio and Talbott,²⁶ or, more simply, by titrimetric determination of the total inorganic sulfate equivalent to it, by the method of Stadie and Ross.²⁷ Obviously, one cannot use sodium oxalate as an anticoagulant for plasma. A convenient method for determining the value of sodium is that of Butler and Tuthill²⁸; for determining the value of potassium, that of Fiske and Litarczek.²⁹ Because different cations have different equivalent weights, it is preferable to speak of their concentrations in terms of milliequivalents per liter of serum or, more scientifically speaking, per liter of serum water. With this re-

duced terminology, the various cations listed below can be added together and considered in toto.

For the uninitiated, the following analogy may clarify the reason for the use of milliequivalents in summing the concentrations of various electrolytes: on a farm it is possible to specify the total number of animals, even though rats, sheep, cows and horses have quite different individual weights.

Several important physiological principles should be remembered in considering the concentration of the various serum bases. The concentration of the total base and of the constituent cations tends to be maintained even under considerable stress, so that the osmotic pressure of body fluids remains nearly constant. Moreover, the liquid outside of cells is in equilibrium across the cell membrane with the cell sap, which has the same concentration of total osmotically active ions as the serum with which it is equilibrated. This is true, of course, only when the concentrations are expressed in terms of equivalents of ions per kilogram of water, because 100 cc. of cells contains only 75 to 85 gm. of water, whereas serum contains 92 gm. of water and transudates 99 gm. Thus, per kilogram of total cell substance (75 per cent water), there are only 112 milliequiv. of total base, as compared with 148 milliequiv. per kilogram of serum. In addition, there is the slight complication that protein itself can bind base.

In general, the organism retains water and base simultaneously to form a sort of Ringer's solution. If extracellular fluid is gained, sodium is retained, but if the new fluid is intracellular, potassium is retained. Individual anions, for example, chloride, are subject to great change, although the summed anions must approximately balance the total base. On the other hand, total base and total anions do not vary greatly, and even individual bases change relatively little. Alterations in metab-

(Mg ⁺⁺)	3~	4
Totals	167	174

olism of total base, therefore, are compensated for by expansion or shrinking of the tissue spaces, which serve as a volume buffer, as described by Gamble.³⁰

Normal values range usually from 160 to 168 milliequiv. per liter of serum water, and ordinari-

ly sodium accounts for over 90 per cent of the total base. In Table 3 the concentrations of the common cations are given in milliequivalents.

Because the total number of positive charges in solution must approximately equal the total number of negative charges, it is evident that the total base must approximately equal the total anions.

method is that of Van Slyke and Sendroy.³¹ Red cells show only half the concentration of plasma, partly because of Donnan's equilibrium.³² Chloride is the most abundant electrolyte and crystalloid constituent of the blood. In sweating, diuresis or a low salt diet, chloride tends to run parallel with sodium. Because the total base, as noted

TABLE 4 Component Cations (Total Base) and Anions (Total Acid) in Normal Serum

Total base = total acid												
Sum of positively charged ions (cations)						= sum of negatively charged ions (anions)						
	Na ⁺	K ⁺	2 Ca ⁺⁺	2 Mg ⁺⁺		Cl ⁻	+ HCO ₃ ⁻	+ f × protein ⁻	+ H ₂ PO ₄ ⁻	+ R ⁺		
Expressed as m l equiv per liter	142	5	5	2		105	+ 25	+ 17	+ 2	+ 5		= 154
Expressed as mg per 100 cc	327	+ 19	+ 10	+ 24		34		f × 100	+ 3.1			
Expressed as vol per cent							48					

*The factor *f* by which the protein concentration is multiplied expresses the net capacity of the combined plasma proteins to bind base at pH = 7.4

†Sulfate + organic acid radicals

Note that the value for the total base is only about 154 milliequiv per liter for serum as compared with 167 milliequiv for serum water (Table 3). This is true because only 92 per cent of serum is water. The values for serum water and cell water that is 167 and 174 milliequiv respectively also differ slightly.

This will be clear from the equations listed in Table 4, which give the typical normal values for the individual components.

Low values for serum water, that is, a fall of 10 per cent or 15 to 20 milliequiv per liter, may occur in severe burns, in marked pyloric stenosis or in terminal nephritis. Representative values in nephritis with edema might be 142 to 156 milliequiv, as compared with 150 to 160 milliequiv without edema. Because the kidney fails to conserve base in chronic glomerulonephritis, late values may be 139 to 149 milliequiv. Similarly, in severe sweating causing heat cramps, the total base may fall to 140 milliequiv, of which sodium supplies 130. In the edema of malnutrition, as in diabetes, the total base may occasionally fall to 130 milliequiv. Of course, the foregoing values all represent concentrations per liter of serum water. Low values are also found in Addison's disease, in Simmonds's cachexia, in major gastrointestinal upsets and in acute poisoning with bichloride of mercury. Even the severe sweating of acute fevers, for example, pneumonia, may induce a definite fall. Of specific interest is the low potassium in familial periodic paralysis.

High values are found in x-ray nephritis, when potassium may increase severalfold. It increases in Addison's disease, for which reason the total base often fails to fall appreciably despite a marked drop in the sodium. High potassium has been described in intestinal obstruction and in acute attacks of Ménière's disease.

Acids

Plasma Chloride

The value for plasma chloride is usually determined by titrating as silver chloride. A convenient

above, varies but little, a change in chloride must ordinarily be compensated for by an inverse change in bicarbonate, and vice versa. Thus, when chloride is low, bicarbonate is usually high. The outstanding exception to this statement is the case in which extraneous acids are present, for example, in diabetic coma. Similarly, after prolonged hyperventilation the low carbon dioxide content of the blood may be accompanied by low sodium and almost certainly by high chloride.

Normal values usually range from 100 to 110 milliequiv. per liter of plasma.

Low values, that is, 98 milliequiv. per liter—the urinary threshold—may be encountered in a salt-free diet, and the urine may be devoid of chloride. Starvation may occasionally reduce the value to 91 milliequiv, as may the sweating leading to heat cramps. After a meal the alkaline tide due to gastric acid secretion may be accompanied by a fall in plasma chloride of 3 milliequiv. On a larger scale, as in pyloric obstruction with repeated vomiting, loss of gastric hydrochloric acid may reduce the serum chloride to less than half its normal value. Indeed, tetany may result, accompanied by a high value for plasma bicarbonate. This obviously cannot occur with achlorhydria because then the vomitus contains approximately equal amounts of sodium and chloride. In diabetic ketosis, despite the accompanying dehydration, the values may fall to 86 or 96 milliequiv as the combined result of vomiting, diuresis, accumulation of oxybutyrate and acidosis. Although edema tends to be aggravated by administration of bicarbonate and salt, the change is usually registered by an increase in intercellular fluid rather than in sodium concentration. In pneumonia there may be a drop to 80 milliequiv, for which reason some clinicians

recommend giving salt up to the point of edema. Similarly, in eclampsia a low chloride concentration is common. The results in nephritis are variable, owing to opposing trends. With edema there may be retention of salt and water in disproportionate degrees so that low, normal or high concentrations of chloride may be found. In the absence of edema, a so-called "dry" retention of chloride may occur; or there may be a chloride deficit, with or without dehydration. In terminal uremia, normal or low chlorides are usual, depending on the extent of vomiting and the effect of the loss of the renal threshold. Accordingly, for the best therapy it is necessary to know simultaneously the total base (or sodium), chloride and carbon dioxide of the serum.³³

High values, up to 110 milliequiv. per liter, may be induced by giving 40 gm. of salt a day. In diarrhea the value is normal or slightly increased. Preceding a diuresis, whether spontaneous or due to mercurial diuretics, it may rise to 120 milliequiv. In acute or chronic glomerulonephritis or in gouty nephritis, there also may be a slight increase.

Infants show extraordinary fluctuations in various illnesses. In bronchopneumonia, values of 79 to 93 milliequiv. per liter have been reported, and in lobar pneumonia 74 to 100 milliequiv. Infantile tetany may show 78 to 100 and nutritional edema 75 to 101 milliequiv. Some of the most bizarre disturbances involving electrolyte balance occur in infants and children.³³

Blood Carbon Dioxide

Because the corpuscles contribute significantly to the binding of carbon dioxide under physiologic circumstances, it is justifiable to use whole blood for this determination. Detailed methods are given by Peters and Van Slyke.³ Nevertheless, in many laboratories plasma is being used. There is the additional complication that one may determine either the *content* at the time when sampled or the combining *capacity* after equilibration with a standard gas mixture like alveolar air. Furthermore, plasma gives different values depending on whether the red cells have been removed before or after equilibration—the so-called "true" or "false" plasma. It is essential, therefore, to know precisely with which combination of these possibilities one is dealing. Probably the most convenient arrangement is the gasometric determination by the Van Slyke apparatus³ of the carbon dioxide combining capacity of the whole blood when equilibrated at 37°C. with a gas mixture containing carbon dioxide at a tension of 40 mm. of mercury and oxygen at a tension of at least 110 mm. of mercury.

Normal values range from 22 to 30 millimols per liter, or approximately 50 vol. per cent.

Low values are commonly found in infantile di-

arrheas, in which treatment by Hartmann's solution³⁴ is preferable to the administration of saline alone. Of course, any reduction in total plasma base will tend to reduce bicarbonate. In severe diabetic coma, the total carbon dioxide may fall to 3 millimols per liter, or 7 vol. per cent. Low values are also found in uremic acidosis owing to the accumulation of inorganic acids (phosphate and sulfate). In hysterical hyperpnea enough carbon dioxide may be blown off to reduce markedly the total carbon dioxide, at least temporarily.

High values occur in emphysema owing to faulty ventilation. They are occasionally found after prolonged treatment with Sippy powders for peptic ulcer. When the value reaches 40 millimols per liter, tetany usually ensues; this concentration corresponds to the absorption (without excretion) of 40 gm. of sodium bicarbonate. Of special interest are paradoxical combinations of acidosis and a high total carbon dioxide, such as may be induced by rebreathing of gas mixtures rich in carbon dioxide. One may likewise find a paradoxical alkalosis associated with a low total carbon dioxide level in the blood, such as that induced by hyperventilation. Such combinations are likely to be overlooked in routine clinical medicine. This error may be avoided by the habitual use of total base, chloride and carbon dioxide in unusual cases involving electrolyte balance.³³ The determination of carbon dioxide in the alveolar air is also helpful if conditions are favorable.

Acidity (pH)

Although the acidity of the whole blood is influenced physiologically by the red cells, it must perforce be determined in plasma. It may be measured with approximate accuracy by the careful use of an indicator, using a comparator device.³⁵ It is better measured electrometrically in a laboratory equipped with a glass electrode³⁶ or similar device, or by the use of gasometric analyses involving carbon dioxide dissociation curves.³²

Normal values range from pH 7.35 to 7.48. Life can exist for only a short time below pH 6.9 or above 7.85.

Low values indicate acidosis, and at pH 7.0, acidotic coma sets in.

High values indicate alkalosis, and at pH 7.8, alkalotic coma occurs.

REGULATORS (VITAMINS, HORMONES, ENZYMES) *Plasma Vitamin A*

The value for plasma vitamin A may be estimated approximately by photoelectric colorimetry, but the problem is still in the investigative phase and normal values are debated. The same statement may be made for plasma carotene. In carotemia the increased color may be mistaken for

icterus, but the identification is easily made because the van den Bergh determination of bilirubin will be normal. Likewise, special identification of the ether-soluble carotene is possible through appropriate tests as described by Stueck, Flaum and Ralli.³⁷

Plasma Vitamin C

The value for plasma vitamin C is ordinarily determined by titrimetric³⁸ or colorimetric³⁹ analysis, involving Tillmann's oxidation-reduction indicator. The concentration in the plasma falls much sooner than that of the tissues in avitaminosis, and indeed falls rapidly in acute febrile infections. Analyses of the plasma may therefore produce false alarms because the tissues may still be moderately well supplied with vitamin when the plasma is devoid of it.

Normal values in the plasma or serum approximate 0.8 mg. per 100 cc., but wide variation in values is reported from different laboratories. Thus the plasma often contains 1.3 to 2.8 mg. and the red cells 0.8 to 1.7 mg. In persons without clinical scurvy the values may go at least as low as 0.1 mg. for considerable periods. In frank scurvy the value is approximately 0.

Plasma Vitamin K

Plasma vitamin K has assumed importance in cases involving the clotting of blood, as in malnutrition, jaundice and hemorrhagic diatheses. It is ordinarily determined in terms of the prothrombin clotting time. Several accurate methods are available, as discussed previously in the *Journal*,² but the so-called "bedside test" of Smith, Ziffren, Owen and Hoffman⁴⁰ serves for routine work. Normal values depend on the procedure involved.

Low values occur most frequently in jaundice, because the presence of bile is essential to the absorption of vitamin K by the intestine. Nevertheless, low values (prolonged prothrombin clotting time) may be encountered in other conditions. Among these are the chronic diarrheas, similar to those encountered in sprue, regional ileitis, hemorrhagic disease of the newborn and various diseases of the liver. The test is of great help, not only in diagnosis and in prophylaxis of hemorrhage, but also in following the effectiveness of therapy. In liver necrosis, the administration of vitamin K may fail to restore the plasma prothrombin level to normal.

Plasma Phosphatase

Alkaline phosphatase. The determination of this enzyme in plasma depends on the amount of organic phosphate converted into inorganic phosphate in a given time under standard conditions^{41, 42} Usually incubation for an hour or longer

is required. The values in the literature are confused because various laboratories have used different procedures and different units. Fortunately, the new Bodansky unit is close to the new Jenner-Kay unit.

Normal values range from 1.5 to 4 units, possibly 7. There is much clinical variation, but typical values follow: hyperparathyroidism 25 units; active localized Paget's disease, 5 to 20 units; active diffuse Paget's disease, 50 to 135 units; active rickets at four months to two years of age, 30 to 165 units. Although alkaline phosphatase is ordinarily employed in conditions involving bone disease, confusion may arise because high values are found in many cases of jaundice.⁴³ Thus with jaundice showing an icteric index above 15 one might possibly find an alkaline phosphatase of 40 units, but the values vary greatly.

Acid Phosphatase. Ordinarily there is only a little acid phosphatase in the plasma. This term means an enzyme that operates optimally in acid solution. Such an enzyme occurs in the prostate gland, however, and Gutman⁴⁴ has shown that in cancer of the prostate a high concentration of this enzyme may appear in the plasma. Such a finding obviously may be of high diagnostic value.

Serum Amylase

Serum amylase, an enzyme that accelerates the hydrolysis of starch or glycogen, has been determined by several methods. A convenient one is that used by Cole.⁴⁵ Each investigator employs his own system of units, so that standard values cannot be given. The most useful clinical finding is the extremely high serum amylase activity found almost invariably in acute pancreatitis. In the diagnosis of acute surgical conditions of the abdomen, this test may be of great value.

Plasma "Hormonal" Iodine

If care is taken to eliminate extraneous iodide, the organically bound iodine of the plasma offers a convenient method of studying thyroid disease.² Reliable practical methods are described by Salter.⁴⁶

Normal values range from 4 to 8 microgm. per 100 cc. (A microgram is one millionth of a gram.)

Low values, that is, from 0.5 to 3.5 microgm. per 100 cc., are encountered in myxedema and cretinism, and in polyglandular syndromes, like Simmonds's cachexia, that involve thyroid failure.

High values are found in hyperthyroidism (Graves's disease), in toxic nodular goiter and in some cases of acromegaly. Such values range from 8 to 18 microgm. per 100 cc. and possibly higher, depending on the degree of thyrotoxicosis. Long-standing cases of so-called "hyperthyroidism," however, may show normal iodine values, presumably

because the thyroïdal stores of iodine have been exhausted.

TECHNICAL DETAILS

The laboratory technician is frequently vexed by the careless preliminary handling of blood samples. The following are typical examples of mishandling that should be avoided: The container is dirty, or the stopper leaks. The blood is clotted. A huge excess of anticoagulant has been used, thus interfering with subsequent analytical procedures. The carbon dioxide content of a blood sample is requested, when inadequate—or no—precautions have been taken to avoid loss of carbon dioxide into the atmosphere. Calcium determination is requested in plasma treated with oxalate, which, of course, removes the calcium. Sodium oxalate is used as anticoagulant when analysis for sodium or for total base is requested. The blood is stale or hemolyzed when received at the laboratory. The patient had not been fasting when the blood was drawn.

* * *

In the foregoing synopsis it has been pointed out that clinical chemistry is merely the essence of physiological investigations in pathologic states. It has been emphasized that so-called "normal" values vary according to the procedure used in the laboratory in which they are determined. Therefore it is essential to discover the normal range under individual circumstances. It has also been pointed out that determinations in serum or plasma are usually preferable to determinations in whole blood, which is a mixture of cells and surrounding fluid. Proper interpretation of these values requires keen insight into physiologic mechanisms at work in disease, and such interpretation must be tempered constantly with common sense. The routine laboratory tests are subject to various fundamental as well as incidental errors, and consequently such data should not take precedence over clean-cut bedside observations. Laboratory data merely supplement careful clinical study of the patient in toto.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27011

PRESENTATION OF CASE

A twenty-four-year old woman entered the hospital complaining of abdominal pain, nausea and vomiting of approximately nine days' duration.

The patient was first admitted to this hospital seven years before her present illness with a history of chronic cough and sputum aggravated by frequent upper respiratory infections. The cough gradually became more severe, the sputum more copious and occasionally associated with hemoptysis. Physical and x-ray examinations confirmed the diagnosis of bronchiectasis in the left lower lobe. The left phrenic nerve was crushed, but there was no alleviation of symptoms, so that fourteen months later the first stage of a lobectomy was performed. Six months later the lobe was removed and an uneventful convalescence followed. The patient remained well and active for the next five years; she married and bore one child. Following her pregnancy she had bilateral breast abscesses.

Three weeks before admission she returned to the Out Patient Department with the following story. Two months previously she started to suffer from migratory pains in the ankles, knees, wrists, fingers, elbows, shoulders and back and the first three of these became red, swollen and tender. The tips of the fingers were blanched and sore. In addition she felt weak and tired, and noticed some palpitation and shortness of breath. She stated that the lymph nodes in her neck were swollen occasionally and that she had lost 12 pounds in weight. For the two weeks prior to admission she had frequency of urination, with nocturia once a night. On examination the patient walked with difficulty because of the pain in her joints. The gums were tender and bleeding, and the anterior cervical lymph nodes tender. The thyroid gland was somewhat enlarged. The middle fingers of both hands were spindle shaped; both ankles and the left knee and wrist were swollen, warm and tender, without limitation of movement. The heart was not enlarged, but there was a loud systolic murmur heard best at the pulmonic area; the blood pressure was 110 systolic, 70 diastolic. The pulmonic second sound

was greater than the aortic second. The temperature was 99.4°F, the pulse 98. Examination of the urine showed a + test for albumin with 4 red and 12 white blood cells per high power field. The patient was ordered to bed for one month on a high caloric, high vitamin diet, but returned nine days later. It appeared that after she had been seen in the Out Patient Department she noticed in her left flank a dull ache that soon shifted to the left upper quadrant and became very severe. This pain kept her awake, was not relieved by position and was accompanied by nausea, vomiting and constipation. She felt feverish and had one chill. She took a laxative and felt much better after a bowel movement. In addition there were burning, frequency and urgency on urination. Although the pain persisted as a dull ache, it did not return in all its severity until the morning of admission, when it was again accompanied by nausea and vomiting. The joint symptoms had improved remarkably and at the time of admission had disappeared completely. She had lost 19 pounds in the previous two months.

The patient had had her tonsils and adenoids removed fourteen years previously. The family history was irrelevant.

On examination the patient was well developed and well nourished, but pale, and she appeared chronically ill. She was very restless and complained of pain in the left flank. The head, eyes, ears, nose and throat were normal. Lobectomy scars were present in the left chest posteriorly and laterally. The heart was not enlarged to percussion and the rhythm was normal, but there was a loud systolic murmur over the pulmonic area and a faint systolic murmur at the apex. The pulmonic second sound was greater than the aortic second; the blood pressure was 110 systolic, 70 diastolic. The left diaphragm was high, the lungs were clear, and there was no shift of the mediastinum. The abdomen was soft, but an area of tenderness was present high in the left flank near the costovertebral angle, with moderate muscle spasm in this area. Pelvic and rectal examinations were negative except for a moderate cystocele. The reflexes were active and equal, and all joints appeared normal.

The temperature was 100°F, the pulse 90, and the respirations 20.

Examination of the urine showed a ++++ test for albumin with 5 to many white blood cells and 10 to 30 red blood cells per high power field. The specific gravity varied from 1.002 to 1.012. Several cultures grew variously colon bacilli, *Staphylococcus aureus*, *Staph. albus* and diphtheroids. Examination of the blood showed a red-cell count of

3,250,000 with a hemoglobin of 55 per cent, and a white-cell count of 14,000 of which 81 per cent were polymorphonuclears, 17 per cent lymphocytes and 2 per cent monocytes, with no eosinophils or basophils. The nonprotein nitrogen of the blood serum was 55 mg. per 100 cc., and a blood culture and a blood Hinton test were negative. The serum protein was 5.8 gm., the phosphorus 7.1 mg., and the calcium 8.7 mg. per 100 cc.; the blood chlorides were 89.8 milliequiv. per liter, and the carbon dioxide combining power was 19.8 milliequiv. per liter. A phenolsulfonephthalein test showed no excretion of the dye in fifteen minutes, and less than 5 per cent in thirty minutes. An intravenous pyelogram showed a large quantity of gas in the small and large bowels, without definitely dilated loops. The kidney outlines were indistinct but sharp where visible; both were grossly enlarged but showed no lobulation. The intravenous dye was excreted poorly. The left kidney pelvis was not definitely visualized; the right pelvis was moderately enlarged, and the calyces appeared distorted, but normal in size. A bilateral retrograde pyelogram showed slight dilatation of the left kidney pelvis and calyces. The right kidney calyces showed multiple irregular deformities. A chest plate showed the old resection of the left seventh and eighth ribs and a high diaphragm on the left side. The left costophrenic angle was obliterated.

A cystoscopic examination showed a normal bladder and normal ureteral orifices. The catheters passed easily into the kidneys, and a normal drip of clear urine was obtained on the right, but none on the left. On the tenth hospital day the patient started to hiccup and vomited a gray fluid, which was guaiac positive. The nonprotein nitrogen had risen to 110 mg. per 100 cc. Four days later catamenia began two weeks early, but the flow ceased within two days. Sixteen days after admission, the patient complained of a "white sheet" in front of her eyes and ringing in the ears. Ophthalmoscopic examination was negative, and she was able to count fingers. A few minutes later she became comatose and rigid, with stertorous breathing, and blood-flecked saliva oozed from her mouth. Consciousness quickly returned with little subjective change, and though she complained of weakness in the lower extremities physical examination was negative except for a questionable temporal-field defect on the left; the blood pressure was 140 systolic, 90 diastolic. The patient appeared to improve for a day, but then became drowsy, and purpuric spots were noticed about the elbows. The next day she had a hemoptysis and complained of a sharp chest pain; bron-

chial rales were heard over the entire right chest. By the following day she was semicomatose, with rapid respirations and slight cyanosis. The pulse rate was 110, and the blood pressure 140 systolic, 90 diastolic; rales were present at both lung bases. The nonprotein nitrogen was 87 mg. per 100 cc., with a carbon dioxide combining power of 16.9 milliequiv. per liter. In the evening she suddenly coughed up 100 cc. of pure blood, and died two and a half hours later, three weeks after admission.

DIFFERENTIAL DIAGNOSIS

DR. WALTER BAUER: I had thought that we members of the arthritic group saw all the patients who came into the medical wards with arthritis. However, this is one we did not see. Since reading the report, I wish we had.

I doubt if the events chronicled in the first paragraph of this patient's history have anything to do with the present illness.

As I see it, my problem is a twofold one: first, to establish if possible the nature of the lesion responsible for the renal failure, and secondly, to determine whether the antecedent arthritis was or was not related to the renal disease. In other words, should I attempt to explain the entire clinical picture on the basis of one disease or should I make several diagnoses? In a young adult, it is usually safer to make one diagnosis. In adults above fifty, it is much more hazardous.

I first thought this patient suffered from pyelonephritis with obstruction of the left ureter, but the subsequent findings do not bear out this diagnosis. The absence of chills and the scanty evidence of fever would be most unusual, and we do not associate any type of arthritis with pyelonephritis.

Bilateral polycystic disease of the kidneys with an associated secondary gouty arthritis would be considered by some. I should hesitate to make such a diagnosis, because I have never been willing to believe that there is such a disease as secondary gouty arthritis, and because the x-ray findings are not like those of polycystic disease of the kidneys.

Could this patient have had nephritis? I should say that she could. The enlarged kidneys would rule out a diagnosis of chronic glomerular nephritis, with secondary hyperplasia of the parathyroid glands and renal osteitis fibrosa cystica. However, enlarged kidneys are seen in acute and subacute glomerular nephritis.

There are many reasons why I should prefer to stick to this diagnosis. It would help explain many other features of this patient's disease. I

believe that she suffered from recurrent attacks of pulmonary edema, a not uncommon finding in acute nephritis. The pulmonary changes occurring under such conditions can be responsible for confusing and bizarre x-ray findings. They may vary greatly from day to day. This type of pulmonary edema is probably another manifestation of the diffuse capillary damage that can take place in acute nephritis.

Can we possibly connect the arthritis with the nephritis? Coburn* has described nephritis as a complication of rheumatic fever. It is usually very mild, and the diagnosis rests largely on the urinary findings. I doubt if it ever progresses to a stage where renal failure would be evident. There are no findings in this record to suggest that the patient was suffering from periarteritis nodosa, nor are the renal findings consistent with this diagnosis. If she had rheumatoid arthritis and nephritis, I should not consider them causally related. The joint involvement was symmetrical, a characteristic finding of rheumatoid arthritis but a rare finding in the other arthritides. However, one very rarely sees red, hot joints in rheumatoid arthritis.

I shall try to rebuild the clinical picture in the following manner: first, a hemolytic streptococcal infection (not recorded in the clinical record); secondly, a specific infectious arthritis resulting therefrom; and finally, the development of an acute glomerular nephritis with complicating pulmonary edema. The sudden exitus may have been due to a cerebral hemorrhage or a pulmonary infarct.

DR. AUBREY O. HAMPTON: The right kidney is much more clearly outlined than the left and is certainly enlarged. After the intravenous dye we see the right kidney pelvis faintly, whereas the left is not visible. In the retrograde pyelograms there are deformities of the right pelvis, but these correspond more closely to the picture of a hypertrophied kidney than to that of a polycystic one. It must be admitted that after a unilateral nephrectomy the pyelogram of the remaining kidney, which undergoes considerable compensatory hypertrophy, may become difficult to distinguish from that of a polycystic kidney. In this case, however, polycystic disease is ruled out by the absence of deformity of the left pelvis. The left ureter is well demonstrated and is normal. The lungs are normal except for a shadow that I interpret as the stump of the resected lower lobe. The diaphragm is high, probably because of the resected lobe. The heart is normal.

*Coburn, A. P. *The Factor of Infection in the Rheumatic State*. 228 pp. Baltimore. Williams & Wilkins Co., 1931. P. 34.

CLINICAL DIAGNOSES

Pyelonephritis with uremia.
Pulmonary infarct?
Pulmonary edema?

DR. BAUER'S DIAGNOSES

Acute specific infectious arthritis (probably due to a hemolytic streptococcal infection).
Late acute or early subacute glomerular nephritis.
Pulmonary edema.
Cerebral hemorrhage?
Pulmonary infarct?

ANATOMICAL DIAGNOSES

Subacute glomerulonephritis.
Cerebral hemorrhage, right occipital lobe.
Periarteritis nodosa.
Hemorrhagic pulmonary edema.
Bronchiectasis, right lower lobe.
Operative scars: lobectomy, left lower lobe; phrenectomy, left.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: At the post-mortem examination we found a pair of very large kidneys, weighing 450 gm., with capsules that stripped with difficulty and left slightly granular surfaces, in other words a subacute nephritis. On microscopic examination all the glomeruli were found to be involved in the typical manner of diffuse glomerulonephritis. There was no evidence of pyelonephritis or of any obstruction in the urinary tract. I cannot explain why the intravenous dye was excreted only by the right kidney. The precipitating factor in death was a cerebral hemorrhage, and that report of questionable visual defect on the left was probably quite correct, because the patient had a large hemorrhage in the right occipital lobe. There was pulmonary edema. There was also some evidence of chronic infection in the base of the right lung, a mild degree of bronchiectasis similar to what had led to operation on the other side. When the microscopic sections came through, we were surprised to find something else. This was most obvious in the spleen, where the arteriole in each Malpighian corpuscle showed a periarterial granulomatous process. Further search quickly revealed numerous arterioles in the pancreas and in the systemic musculature, with lesions typical of periarteritis nodosa.

There certainly was nothing in the clinical history or physical findings remotely pointing toward such a diagnosis. Dr. Bauer raised the question of

rheumatic fever. The valves were quite negative, and we could find no Aschoff bodies in the myocardium; consequently, we have no positive evidence of it. On the other hand, periarteritis nodosa is seen in association with rheumatic fever with significant frequency, so that one might argue that the periarteritis was evidence of rheumatic infection. I do not know how that can be disproved.

DR. BAUER: Do you think there is any possibility of explaining everything on the basis of acute nephritis following a hemolytic streptococcal infection, which had caused the antecedent infectious arthritis? That would explain everything that occurred in this patient.

DR. MALLORY: That explanation is certainly adequate for everything except the arterial lesions. They bring up the old problem. Is periarteritis nodosa a specific disease with a single though unknown etiology, or is it possible that such lesions can develop in the course of a variety of different pathologic entities? Reliable evidence that they occur in any disease of known etiology is lacking, so that I am still slightly predisposed in favor of the first hypothesis.

CASE 27012

PRESENTATION OF CASE

A forty-nine-year-old Swedish machinist entered the hospital complaining of increasing shortness of breath and substernal pain of two years' duration.

At nine years of age, the patient spent one week in a hospital because of swelling of his feet, but could recall no other features of this illness. At fourteen he fell into the water during the winter, and for the next two weeks his feet and ankles were swollen. Each spring thereafter the swelling recurred and lasted for about a week. The patient immigrated to the United States at the age of twenty-two, and at this time noticed slight palpitation, but was able to do manual labor without distress. At twenty-seven he spent eight weeks in bed with the "flu." Two years before entry he first noticed the onset of shortness of breath and substernal pain with palpitation. In the last four months the attacks were frequent and often lasted for several minutes. The patient continued to work steadily in a shoe factory until eight weeks before entry, when his physician told him to "take it easy." He worked spasmodically until the time of admission, when an increase in the above symptoms, in addition to insomnia and anorexia, forced him to give up. He stated that he had had frequent nosebleeds for the two or three years prior to entry.

The family history was irrelevant.

On examination the patient was a well-developed, slightly jaundiced man who was dyspneic and appeared chronically ill. The neck veins were distended. Examination of the heart revealed marked enlargement to the left and a rapid, completely irregular impulse. There was a systolic murmur at the apex, and diastolic and systolic murmurs at the left sternal border. The blood pressure was 120 systolic, 80 diastolic. The lungs were clear. The liver was slightly tender and palpable four fingerbreadths below the right costal margin. There was no edema of the extremities.

The temperature was normal, the pulse 70, and the respirations 28.

Examination of the urine showed a +++ test for albumin, with frequent hyaline and granular casts. The blood showed a red-cell count of 4,470,000 with a hemoglobin of 14.5 gm. (photoelectric-cell technic), and a white-cell count of 15,600 with 70 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 59 mg., and the van den Bergh 4.7 mg. per 100 cc. A blood Hinton test was negative.

X-ray examination of the chest showed a grossly enlarged heart, the enlargement affecting all chambers. The hilar shadows were prominent, and there was hazy density extending out into both mid-lung fields. At a subsequent examination there was diffuse dilatation of the pulmonary vessels without fluid in the pleural cavities. The auricles were grossly dilated, and the apex of the heart was thick and blunt. The aorta was relatively prominent. No areas of calcification were seen in the region of the valves or the pericardium. The electrocardiogram showed auricular fibrillation; there was slight to moderate left-axis deviation, and the QRS interval in leads 1 and 3 measured from 5 to 6 mm.

Following digitalization the ventricular rate was slowed, the heart decreased in size and the non-protein nitrogen of the blood serum dropped to 25 mg. per 100 cc. At times the patient was restless and nervous, apparently because of dyspnea. A decrease in fluid output led to the use of Salycan, with satisfactory diuresis. A phenolsulfonephthalein test at this time gave a 20 per cent excretion in fifteen minutes, 50 per cent in thirty minutes. The patient gradually improved and one month after admission was allowed to sit in a chair and walk about the ward. Although this activity was performed without distress, he became dyspneic with any increase in exercise. Six weeks after admission he began to go downhill, gradually became confused and disorientated, and developed Cheyne-Stokes breathing and sacral edema, with an increased pulse rate. The tem-

perature rose abruptly to 101°F. and then to 104 with a white cell count of 13,700, but the lungs were still clear. One week later the patient became semicomatose, and he died the next day, seven weeks after admission.

DIFFERENTIAL DIAGNOSIS

DR. PAUL D. WHITE: We should like to know more, particularly in regard to the details of the shortness of breath and of the substernal pain. We should also like to know whether that substernal pain was related to effort or came on in paroxysms when the patient was in bed. It seems to have been a rather indefinite pain, which might or might not have been angina pectoris.

A forty-nine-year-old man may have substernal pain and dyspnea due to either coronary disease or syphilitic aortitis. These are the two types of heart disease that come to mind first. Of course, too, he might have had a condition that had been present since early life. The swelling of the feet at the ages of nine and fourteen may have been due to a variety of things, but we naturally think of rheumatic fever. "Each spring thereafter the swelling recurred and lasted for about a week." Spring is the time, of course, when we might expect recurrence of a rheumatic infection. We should like to know if there was any statement about pain, as well as swelling of the feet.

DR. BENJAMIN CASTLEMAN: There was none.

DR. WHITE: Generally joint pain is more pronounced than swelling in acute rheumatic infection, but sometimes there is surprisingly little of either. Finally, there is a suggestion of active rheumatic fever in the story of repeated nosebleeds, but we cannot consider it a reliable indication. Rheumatic fever is not rare in Sweden, and rheumatic heart disease is frequently found throughout northern Europe.

"At twenty-seven he spent eight weeks in bed with the 'flu.'" That was twenty-two years before admission, and would bring it about the time of the great influenza epidemic. He probably had "flu" and pneumonia with it.

We may guess that the patient had had recurrent attacks of rheumatic fever, but up to the time of his immigration to this country he had had no symptoms of heart disease other than palpitation, too minor a symptom to be of importance. Since entering this country he had been quite active in manual labor. He was either a casual or a stoical Swede, I should say, certainly not neurotic, and probably rather neglectful of his health, since he continued to work despite his symptoms during the last two years.

I should like to know why he had insomnia,

also if the anorexia occurred when he began to be congested and to have dyspnea. Insomnia is sometimes due to dyspnea or orthopnea. I have seen patients benefited more by digitalis than by hypnotics.

Auricular fibrillation is evident. Its onset may have been the precipitating cause of his increase of symptoms during the past two years. It is a point against syphilis, and also against coronary disease at this time.

The systolic murmur at the apex is not very important, except that it means that there is something wrong. Even if it is loud, such a murmur may be the result of functional mitral regurgitation without any intrinsic heart disease. The diastolic and systolic murmurs at the left sternal border are another thing. What they mean we cannot be sure—probably aortic regurgitation. Most patients who have aortic regurgitation with a diastolic murmur along the left sternal border have also a systolic murmur.

The blood pressure measurement is evidence against a diagnosis of free aortic regurgitation. There is no increase in pulse pressure, so that we may assume that the aortic regurgitation causing this murmur was slight or that the murmur was due to pulmonic regurgitation. Pulmonic regurgitation may occur secondary to mitral stenosis, but we should find evidence of marked stenosis before that happens, and no such evidence is present.

"Examination of the urine showed a +++ test for albumin, with frequent hyaline and granular casts." That is not a diagnostic finding, it may be merely a part of the congestion.

"The nonprotein nitrogen of the blood serum was 59 mg, and the van den Bergh 47 mg per 100 cc." They are elevated, but neither one of itself is diagnostic evidence of kidney or liver disease.

"A blood Hinton test was negative." That is a very important point, because with a man of this age aortic regurgitation brings to mind syphilitic aortitis. The chances are nine to one that there is no aortitis in the presence of a negative Hinton test.

There was an increase in the shadow of the pulmonary vessels during life, which is not shown in the post-mortem film. That may be due to failure of the left ventricle rather than to pulmonary disease or mitral stenosis.

The patient had quite a good recovery, but slow. It was a month before he was allowed to sit up.

"Six weeks after admission he began to go down hill, gradually became confused and disorientated, and developed Cheyne-Stokes breathing and sacral edema, with an increased pulse rate." Why this

disappointing development? He was getting on all right, and for no obvious reason he began to do poorly, with increasing pulse rate and cardiac failure, despite good therapy. Something new had happened. Was it infection, or possibly infarction? If it was infection, might it be recurrent rheumatic infection? There is no indication of subacute bacterial endocarditis, which is rare in the presence of auricular fibrillation. There may be rheumatic endocarditis or infarction of lungs without physical signs. There may even be myocardial infarction without symptoms or signs.

To sum up, let us take the known findings first. The patient had a big heart, auricular fibrillation and total heart failure. Those are the three things that are quite clear. He probably had aortic regurgitation. Once in a while there may be aortic regurgitation due to syphilitic aortitis, without valve deformity. A dilatation of the aortic ring may account for insufficiency of the valve, which will not be found at autopsy. We may know it is there clinically, but we do not put down organic aortic regurgitation as an essential finding at autopsy. Mitral regurgitation, with or without mitral valve disease, was present. We know that the patient had a big heart, and he might have had mitral regurgitation secondarily, but whether or not he had valve disease we cannot tell. With failure, a big heart may have mitral stenosis (or aortic stenosis) of a considerable degree without the characteristic murmurs. Finally, he may have had terminal pulmonary infection or infarction. In favor of infarction is the jaundice and the elevated serum van den Bergh.

Now comes the difficult problem, namely, the question of etiology. The best bet in view of the childhood history, the aortic regurgitation and the auricular fibrillation is rheumatic heart disease, acute and chronic. Coronary disease is less likely, and if present is superimposed. We do not see auricular fibrillation so frequently from coronary insufficiency, and we expect death more suddenly. Syphilitic aortitis is possible but not probable; it may be a complication. We have had patients with rheumatic heart disease and syphilitic aortitis combined, but I do not believe that diagnosis is more than a possibility here. Syphilitic aortitis and subacute bacterial endocarditis must be considered as unlikely possibilities. I should say that there was a complicating infection or infarct, with pulmonary infarction as a first guess.

DR. HOWARD B. SPRAGUE: I am glad to have Dr. White go through the same course of thought that I did on seeing this patient. He came to the Out Patient Department and was admitted on the service. One of the admission diagnoses was coro-

nary disease. He had rapid auricular fibrillation, and it was very difficult to make out anything in the examination of the heart. A house officer noted a systolic murmur. When I examined the patient a little later I made the following note in the history:

The history suggests repeated rheumatic infection of the ankles and feet in childhood. His recent progressive dyspnea and palpitation may have been brought on by auricular fibrillation, which he now shows. He has a big, forceful heart with a systolic murmur at the apex and a systolic and diastolic at the left sternal border. I believe he has a rheumatic heart with mitral regurgitation, and possibly some stenosis, and aortic regurgitation, with again a question of stenosis. The fever suggests active endocarditis, pulmonary embolism or phlebitis.

He was digitalized, given mercurials, and during the next three or four days the murmurs became obvious on examination. There was a note of a systolic murmur at the aortic area, without any thrill. He then, as has been recounted, failed to make satisfactory progress, and again we asked if this were active rheumatic infection in the heart or in the lung or multiple small pulmonary infarcts, or thrombosis elsewhere in the body that we could not discover.

DR. WHITE: Did the aortic systolic murmur become more distinct when he improved?

DR. SPRAGUE: Yes.

DR. WHITE: It raises the question of aortic stenosis, of course. It may be very difficult to detect aortic stenosis in the presence of congestive failure because of the decrease of blood flow. I should like to add the diagnosis of aortic stenosis as a possibility here.

CLINICAL DIAGNOSES

Rheumatic heart disease, with combined aortic and mitral valvular lesions.
Acute bacterial endocarditis?
Cavernous sinus thrombosis?
Cerebral emboli?

DR. WHITE'S DIAGNOSES

Rheumatic heart disease, with aortic regurgitation, ? aortic stenosis and relative mitral regurgitation.
Hypertrophy of the heart.
Auricular fibrillation.
Pulmonary embolism or infarction.
Chronic passive congestion.

ANATOMICAL DIAGNOSES

Aortic stenosis, calcareous.
Septicemia (hemolytic streptococcus).
Cerebral and cerebellar degeneration.
Cardiac hypertrophy.

Mural thrombus, right auricular appendage.
Pulmonary infarction, recent.
Chronic passive congestion of lungs, liver and spleen.
Arteriosclerosis, coronary and aortic.
Icterus.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy this man had an unusually large heart, weighing 800 gm. There was hypertrophy and dilatation of all chambers. The mitral valve was perfectly normal in appearance, although it measured 12.5 cm. in circumference. There was no thickening of the margins or of the chordae tendineae to suggest rheumatic infection. The aortic valve showed marked stenosis of the calcareous type, with a lumen that admitted the tip of the index finger, probably 0.5 cm. in diameter. The valve itself measured 4 cm. in circumference. Almost all the deposits of calcium were on the sinus side of the cusps, and the appearance was characteristic of the Mönckeberg type of calcific aortic stenosis. There was no intercalation of the cusps at their commissures, such as is seen in typical rheumatic endocarditis. There were no other valvular lesions. The coronary arteries showed a fairly extensive arteriosclerosis, but no evidence of occlusion. Microscopically there were small foci of scarring in the myocardium, which may have accounted for his anginal pain, although we have seen cases of aortic stenosis alone without coronary disease associated with an-

ginal pain. The lungs had several infarcts at both lower lobes, the emboli probably arising from mural thrombi in the right auricular appendage. The leg veins were not examined. The combination of congestion in the liver, which was moderately severe, and pulmonary infarction adequately explains the jaundice.

It is quite possible that the disease the patient had in childhood was not rheumatic fever but some other infection that may have involved the aortic valve.

DR. WHITE: You would agree that there was probably an infectious form of aortic-valve involvement before the calcification?

DR. CASTLEMAN: Yes. Whether or not it was rheumatic, I am not sure.

DR. SPRAGUE: After Dr. Castleman found this, we went back over the autopsy cases of aortic stenosis to see if the presence of auricular fibrillation had often confused the diagnosis of aortic stenosis. I think that this can be said to be true. Rapid auricular fibrillation with severe failure, uncontrollable by digitalis, may obscure the characteristic features of the murmur and thrill at the aortic area, and the diminished aortic second sound may be erroneously attributed to cardiac failure alone.

DR. WHITE (later note): The apparent, insistent history of recurrent rheumatism in this patient favors, I think, rheumatic infection as responsible for the aortic stenosis, with superimposed calcification.

THE NEW YEAR

NEARLY twenty centuries ago an apparently new star of great magnitude was observed in the east; whether this was a new comet or the conjunction of two or more heavenly bodies is today of relatively little importance. What is of significance is the belief that this star was the celestial sign of a new order beginning in the eastern world—an order based on the humanity of man to man under the leadership of the founder of Christianity.

The season of Christ's birth is probably not exactly known, nor is it of any great importance. It is perfectly natural, however, that it should have finally been placed, as accurately as the early astronomers were capable of determining the occasion, at the time of the new year. It is an acci-

dent that both Christmas and the New Year should have been established on dates that follow the winter solstice by several days; it is no accident that they should have been so closely linked together at that period of the year when the retreating sun pauses before commencing its northward journey, and the darkness of the world begins to give way before the promise of light.

That the physical illumination of the world should be in this way identified with the spiritual enlightenment of mankind seems peculiarly fitting, and it is altogether proper that our festival season of greatest solemnity and yet of greatest joy should be thus annually renewed.

This year, curiously enough, when some of the darkest days through which Christianity has passed are so recent in our memories, again a new star has appeared; this time in the west. We do not dare allow our hopes to leap too high, or our emotions to outride our reason, but if ever an omen for a new year should be revealed, this is the year when it would be most welcome.

VIRUS PNEUMONIA AND Q FEVER

WELCOME indeed is the news that the causative agent of a number of puzzling cases of atypical pneumonia, due to none of the common pathogenic bacteria, has finally been isolated and identified. This information comes from two different sources,^{1, 2} and the reports appeared almost simultaneously.

In recent years, with the increasing interest in the etiologic aspects of pneumonia in relation to specific serotherapy and chemotherapy, many physicians in widely scattered localities have noted numerous cases of pulmonary infections of varying severity, but usually not fatal, in which the causative agent has not been determined by ordinary bacteriological methods. Furthermore, with the highly organized health services now available in many large universities and hospitals, it is not surprising that many of these cases of so-called "pneumonitis" or "atypical bronchopneumonia" are reported as occurring among university students and hospital personnel. Another important

factor in the recognition of these atypical pneumonias is the increasing use of roentgenograms of the chest in patients with acute febrile systemic diseases, even when symptoms of pulmonary involvement are minimal or absent.

The reported cases have followed a more or less characteristic clinical course. This has been described recently by several observers, each of whom has reported outbreaks in different parts of this country. One of the two most recent epidemics attacked fifteen employees in the laboratories of the National Institute of Health in Washington, one of whom died.¹ All these patients had high temperatures; profuse sweating frequently occurred, but true chills were rare. They felt ill and exhausted but did not have the breathing difficulty of patients with true pneumonia, or the severe body aches and pains of those with influenza. X-ray examination of the chest was found to be necessary to detect specific lesions in the lungs. It is stated, "A comparison of the clinical features and physical findings in these cases with various series reported from other sections of the United States in the past few years reveals suggestive similarities." Laboratory investigation revealed a rickettsia very similar to the one that causes Q fever in Australia. It was isolated from the blood of two of the recovered cases, and from the spleen of the fatal case.

Q fever was first described in Queensland in 1937.² A species of *Rickettsia* was recovered from cases of this disease and was shown to be distinct from other known rickettsiae.⁴ Work on this particular disease has been in progress at the National Institute of Health since the spring of 1938; however, not one of the fifteen cases in the recent epidemic occurred in the wing of the building where the experimental work on Q fever was being conducted. Even more remote is linking of these cases to the recovery by officers of the United States Public Health Service, from ticks gathered in Montana, of a rickettsia that caused infection in man and was shown to be very closely related to that of Q fever.⁵

It is interesting that the clinical syndrome and the epidemiology of Q fever in Australia and of

the pneumonitis observed in this country differ in some important respects. Pulmonary signs or symptoms have not been recognized in the former cases, although other features, particularly the type of fever and the severe headache, have been similar. It is possible, however, that pulmonary lesions passed unnoticed because the opportunities for roentgenography were much more limited than they are in America. Both the manifest and the latent Australian cases occurred almost entirely among butchers working in abattoirs, among foresters and among the members of the staffs of laboratories where work with the virus was being conducted. The bandicoot, a common rodent of the Australian bush, was shown to be susceptible and to be one of the reservoirs of infection, and one of the ticks commonly found in the vicinity was proved to be capable of serving as a vector.

The success of previous attempts to isolate a virus from cases of atypical pneumonia in this country was, at most, only suggestive.⁶ Just after the publication of the studies at the National Institute of Health, however, there appeared a report of an investigation conducted by the International Health Division of the Rockefeller Foundation.⁷ These workers recorded the isolation of a filterable virus from the pharyngeal washings of four patients with acute pneumonitis that was capable of producing pulmonary consolidation following intranasal inoculation in the wild mongoose. The etiologic relation of the virus to the human and the experimental disease was established by demonstrating the development of neutralizing antibodies in the course of convalescence from the infection. The mongoose—an animal similar to the ferret, which has been so helpful in the studies of influenza—is not susceptible to known strains of influenza virus. Importation of the animal into this country is prohibited, so that the investigations were carried out in Kingston, Jamaica, with infected materials obtained in New York City.

It remains to be seen whether the workers at the National Institute of Health and those of the Rockefeller Foundation are dealing with the same agent or virus. It seems likely that many living agents, related and unrelated, will ultimately be

implicated, and these studies will undoubtedly stimulate further research, as did those concerned with the discovery of the viruses of influenza. One may now look forward to the rapid unfolding of many interesting aspects in regard to virus pneumonias.

MEDICAL EPONYM

FOWLER'S POSITION

In an article entitled "Results in Diffuse Septic Peritonitis Treated by the Elevated Head and Trunk Position" in *Medical News* (84:1011, 1904), Russell S. Fowler (1848-1906), surgeon to the German Hospital, Brooklyn, New York, describes this position as follows:

Directly after operation the patient is placed in the elevated head and trunk position. This may be done by placing a chair or stool beneath the head-piece of the bed. At the German Hospital, we employ a frame consisting of two side supports and a central bar connecting the two. . . . This frame is secure and allows of different levels being employed. The elevation should never be less than one foot. A folded pillow is placed against the buttocks and through the fold of the pillow is passed a stout bandage which is tied on each side to the head of the bed. This allows the patient to rest comfortably, and maintains his position without exertion on his part.

PREGNANCY IN A PATIENT WITH PRE-EXISTING, COMPLETE HEART BLOCK

Mrs. L. B., a twenty-eight-year-old primipara, was first seen in the hospital on August 28, 1928,

when approximately two months pregnant, because of threatened miscarriage.

The family history was unknown. The patient's early medical history was noncontributory. It had been known that the patient since the age of twelve years had had a very slow pulse. She had no symptoms referable to the heart, however, until the age of nineteen, when she suddenly fainted while playing field hockey and later was told that she had almost died. In 1925 an electrocardiogram showed complete auriculoventricular dissociation, and a diagnosis of complete heart block was made. Comparatively speaking, the patient was free from any cardiac symptoms. Catamenia began at thirteen, were regular with a twenty-eight-day cycle and lasted three to four days with no discomfort. The last normal period began on June 20, making the expected date of confinement March 27, 1929.

About ten days before she was seen in the hospital the patient had a little bloody discharge. This was followed by a slight amount of staining. Physical examination showed a tall, rather thin woman who looked the picture of health. The physical examination was negative, except for the heart, which was slightly enlarged. The apex was seen and felt in the fifth intercostal space 9.5 cm. from the midsternal line, and the left border of dullness corresponded to the same area. The right border was 3 cm. from the midsternal line, and the supracardiac dullness was 5.5 cm. in width. The cardiac rate was 44 per minute, with slight sinus arrhythmia. The heart sounds were of good quality. The auricular sounds were not discernible. There was a harsh, loud, rather musical systolic murmur heard best at the apex but present all over the precordium. The blood pressure was 110 systolic, 70 diastolic. Vaginal examination showed the cervix in the normal axis, the fundus retroverted.

Once a month during the following weeks of pregnancy the patient returned to the hospital for twenty-four hours. She was examined and weighed. A twenty-four-hour urine analysis was made, and an electrocardiogram and a seven-foot plate of the heart with fluoroscopic examination were obtained at each visit. At no time were there any serious symptoms referable to the heart. The patient gained weight slowly; the blood pressure remained between 120 and 130 systolic, 70 and 80 diastolic. There was a slight increase in the rate of both the ventricles and auricles. Toward the end of December she became somewhat overtired, and complained of palpitation and a sense of constriction in the precordium toward the end of the day. She was advised to rest more, and at her next visit all the cardiac symptoms had disappeared; they did not recur.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

On March 20, 1929, the patient was admitted to the hospital to stay at rest until she went into labor. Examination during this period showed the cervix to be entirely obliterated and very soft; the head was well engaged. She was therefore allowed to go into normal labor, which she did after spontaneous rupture of the membranes at noon on March 31. At 3:00 p.m. she was having unsatisfactory pains and was given subcutaneously 2 minims of Infundin. Labor started satisfactorily and continued until 4:30 p.m., when the pains let up somewhat, and she was again given 2 minims of Infundin. Inhalation of nitrous oxide was started as an analgesic at this time. At 5:30 p.m. the head was in sight, and under ether anesthesia a low-forceps delivery was done.

The child was normal in every way and cried immediately. During labor the patient's pulse reached a maximum rate of 76 and was of good quality; the patient was warm and pink. The cardiac rate dropped to 60 immediately after delivery and to 44 at the time of discharge from the hospital, three weeks after the baby was born.

Examination of the heart one year and eight months after delivery showed the auricular and ventricular rates to be the same as before pregnancy; the size of the heart by x-ray films and by percussion was essentially the same. The heart sounds were of good quality; the loud systolic murmur was still present but had not changed in intensity or type.

Comment. This case was reported in the November, 1931, issue of the *American Journal of Obstetrics and Gynecology*. It is referred to again because of its rarity and in an attempt to show that heart block in itself is a contraindication neither to pregnancy nor to pelvic delivery.

POSTGRADUATE EXTENSION COURSES

The postgraduate extension courses are sponsored by the Massachusetts Medical Society in cooperation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau. Registration is free to all legally registered physicians of the Commonwealth. For further information the district chairman of postgraduate instruction should be consulted.

The programs for the winter sessions are as follows:

MIDDLESEX EAST DISTRICT: MELROSE

SUBJECT	DATE
Recent Advances in Medical Therapeutics: Sedatives; analgesics; cathartics; sulfanilamide compounds; dangerous drugs	January 7

The Clinical Recognition of the Types of Jaundice and Recent Advances in Their Treatment	January 14
Chemotherapy in the Treatment of Gonococcal Infection	January 21
Pediatric Case Discussions	January 28
Diagnosis and Treatment of Minor Lesions of Rectum and Anus	February 4
Technic and Treatment of Primary, Secondary and Tertiary Syphilis	February 11
Obstetric Infections: Diagnosis and treatment	February 18
Head Colds and Complications	February 25
Meetings to be held at the Melrose Hospital, Tuesdays, at 4:15 p.m.	

Walter H. Flanders, M.D., *Chairman*
28 Rowe Street, Melrose

MIDDLESEX SOUTH DISTRICT: CAMBRIDGE

SUBJECT	DATE
Management of Abdominal Distention	January 7
Pediatric Case Discussions	January 14
Technic and Treatment of Primary, Secondary and Tertiary Syphilis	January 21
Diet and Vitamins in Surgery	January 28
Obstetric Complications with Case Histories and Clinical Problems	February 4
Chemotherapy in the Treatment of Gonococcal Infection	February 11
Acute Abdominal Pain: Its interpretation and management	February 18
Recent Advances in Medical Therapeutics: Sedatives; analgesics; cathartics; sulfanilamide compounds; dangerous drugs	February 25
Meetings to be held at the Cambridge Hospital, Mt. Auburn Street, Tuesdays, at 4:00 p.m.	

Dudley Merrill, M.D., *Chairman*
51 Brattle Street, Cambridge

NORFOLK DISTRICT: NORWOOD

SUBJECT	DATE
Obstetric Complications with Case Histories and Clinical Problems	January 9
Dermatitis and Eczema (see below for questions to be discussed)	January 16
Diagnosis and Treatment of Minor Lesions of Rectum and Anus	January 23
Technic and Treatment of Primary, Secondary and Tertiary Syphilis	January 30
Acute Abdominal Pain: Its interpretation and management	February 6
Recent Advances in Medical Therapeutics: Sedatives; analgesics; cathartics; sulfanilamide compounds; dangerous drugs	February 13
Chemotherapy in the Treatment of Gonococcal Infection	February 20
Pediatric Case Discussions	February 27
Meetings to be held at the Norwood Hospital, Thursdays, at 8:30 p.m.	

Hugo B. C. Riemer, M.D., *Chairman*
Norwood. Office: 128 Newbury Street, Boston

NORFOLK SOUTH DISTRICT: QUINCY

SUBJECT	DATE
Chemotherapy in the Treatment of Gonococcal Infection	January 6
Diagnosis and Treatment of Minor Lesions of Rectum and Anus	January 13
Obstetric Infections: Diagnosis and treatment	January 20
Recent Advances in Medical Therapeutics: Sedatives; analgesics; cathartics; sulfanilamide compounds; dangerous drugs	January 27
Dermatitis and Eczema (see below for questions to be discussed) . .	February 3
Pediatric Case Discussions	February 10
Nutritional Deficiencies and the Uses of Preparations of Vitamins . .	February 17
Diagnosis, Treatment and Prognosis of Central-Nervous-System Syphilis. . .	February 24
Meetings to be held at the Quincy City Hospital, Mondays, at 8:30 p.m.	

David L. Belding, M.D., *Chairman*
Hingham. Office: 80 East Concord Street, Boston

SUFFOLK DISTRICT: BOSTON

SUBJECT	DATE
Head Colds and Complications	January 9
Therapeutic Uses of Preparations of Endocrine Glands: Thyroid gland, pituitary gland, ovary, testis and adrenal cortex	January 16
Pediatric Case Discussions .	January 23
Chemotherapy in the Treatment of Gonococcal Infection . .	January 30
Dermatitis and Eczema (see below for questions to be discussed) . .	February 6
Acute Abdominal Pain: Its interpretation and management . .	February 13
Diagnosis, Treatment and Prognosis of Central-Nervous-System Syphilis.	February 20
Obstetric Complications with Case Histories and Clinical Problems . .	February 27

Meetings to be held in John Ware Hall, Boston Medical Library, Thursdays, at 4:30 p.m.

Reginald Fitz, M.D., *Chairman*
319 Longwood Avenue, Boston

The following questions will be discussed in the course on dermatitis and eczema:

- Is there such a thing as eczema?
- Is allergy fact or fiction?
- Are skin tests of value in dermatology?
- Are fungous infections (athlete's foot) as prevalent as we are led to believe?
- With the diagnosis made, what should be the treatment of common cutaneous eruptions?

FACULTY FOR THE EXTENSION COURSES

Dermatology. Chairman: Dr. John G. Downing; instructors: Drs. John Adams, Jr., Leonard E. Anderson,

Bernard Appel, J. Harper Blaisdell, G. Marshall Crawford, Francis P. McCarthy, Mildred L. Ryan, Jacob H. Swartz and Maurice M. Tolman.

Ear, Nose and Throat. Chairman: Dr. LeRoy A. Schall; instructors: Drs. Charles T. Porter, Lyman G. Richards and John R. Richardson.

Gonorrhea. Chairman: Dr. Oscar F. Cox; instructors: Drs. Sylvester B. Kelley and P. N. Papas.

Medicine. Chairmen: Drs. Chester S. Keefer and Robert T. Monroe; instructors: Drs. Fuller Albright, Clifford L. Derick, E. Stanley Emery, Eugene C. Eppinger, Marshall N. Fulton, G. Philip Grabfield, Franz Ingelfinger, Charles A. Janeway, Harold J. Jeghers, William T. Salter, Charles L. Short and Maurice B. Strauss.

Obstetrics. Chairmen: Drs. Meinolf V. Kappius and Roy J. Heffernan; instructors: Drs. Christopher J. Duncan, M. Fletcher Eades, A. Gordon Gauld, Thomas R. Goethals, James C. Janney, Foster S. Kellogg, Joseph W. O'Connor, Louis E. Phaneuf, John Rock, Judson A. Smith and Raymond S. Titus.

Pediatrics. Chairmen: Drs. Warren R. Sisson and James M. Baty; instructors: Drs. Elmer W. Barron, John A. V. Davies, Louis K. Diamond, R. Cannon Eley, Joseph Garland, Harold W. Higgins, Lewis W. Hill, Edwin H. Place and Clement A. Smith.

Surgery. Chairmen: Drs. Howard M. Clute and Leland S. McKittrick; instructors: Drs. Hollis L. Albright, Arthur W. Allen, Franklin G. Balch, Jr., Marshall K. Bartlett, William E. Browne, Richard B. Cattell, Edward A. Edwards, Henry H. Faxon, Jacob Fine, E. Parker Hayden, Thomas H. Lanman, Robert R. Linton, Charles C. Lund, Champ Lyons, Henry C. Marble, E. Everett O'Neil, Neil W. Swinton and Irving J. Walker.

Syphilis. Chairman: Dr. Francis M. Thurmon; instructors: Drs. William P. Boardman, Rudolph Jacoby and C. Guy Lane.

TEACHING CLINICS IN GONORRHEA AND SYPHILIS

The Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health and the United States Public Health Service is again sponsoring teaching clinics in gonorrhea and syphilis. Registration in these teaching clinics is free; all expense of teaching is met by the sponsoring organizations. Clinic schedules are listed below; any legally registered physician in the Commonwealth may attend for one or more days.

Gonorrhea Clinics at the Boston Dispensary. These are open daily from 9:30 to 11:30 a.m., and on Monday, Wednesday and Friday evenings from 6:00 to 8:00. Dr. Oscar F. Cox is in charge. Write or telephone for additional information: Gonorrhea Clinic, Boston Dispensary, Boston.

Syphilis Clinics at the Massachusetts General Hospital. These are held in the Out Patient Department, South Medical Service, on Tuesday and Wednesday from 10:00 a.m. to 12:00 noon. Dr. G. Marshall Crawford is in charge. Write or telephone for additional information: South Medical Service, Massachusetts General Hospital, Boston.

POSTGRADUATE EXTENSION LIBRARY

The Massachusetts Medical Society through the cooperation of the Massachusetts Department of Public Health and the United States Public Health Service plans to provide library extension service in connection with the Society's program of postgraduate education. The funds have been provided by the United States Public Health Service, the Boston Medical Library will be charged with the operation, purchase of books and so forth, and with loaning them to physicians by mail or express.

This library service will be ready in the near future, details will be published in the *Journal*. Lists of references about each course will be available at the postgraduate extension courses. Further information may be obtained by addressing Medical Library Extension Service, 8 Fenway, Boston.

MISCELLANY

NEW TUFTS SCHOLARSHIPS

The Charles Hayden Foundation, through its president, J Willard Hayden, has awarded a grant of \$10,000 to Tufts College Medical School to be used for scholarships for selected members of the entering class in that school next fall.

Following the regular plan of the Charles Hayden Memorial Scholarships in other institutions, a portion of this total will be used for outright scholarships during the first year of medical study. The remainder will be held as a special loan fund to be used in upper-class years by those who hold Hayden scholarships during the first year.

Dr Leonard Carmichael, president of Tufts College, in announcing the gift hailed it as a definite benefit to able and worthy young men who might otherwise be debarred from entering the medical profession. He added that the addition of these scholarships will help further the college's aim of training young men who look forward to careers as modern general practitioners. Since the Tufts College Medical School trains more doctors for New England than any other medical school in the country, President Carmichael stated, the gift will be welcomed by the communities throughout this section, as well as by needy and capable students.

Dr Cadis Phipps will serve as chairman of the committee administering the scholarship grants.

NOTE

On December 16, Dr Frank H Lahey, of Boston, delivered the second Floyd Wilcox McRae Memorial Lecture before the Fulton County Medical Society, of Atlanta, Georgia. The title was 'The Management of Gastric, Duodenal and Jejunal Lesions.'

NOTICES

ANNOUNCEMENT

A H DELMAN, M.D., announces the removal of his office from 479 Beacon Street, to 371 Commonwealth Avenue, Boston.

HARVARD MEDICAL SOCIETY

There will be a meeting of the Harvard Medical Society on Tuesday, January 14, in the amphitheater of the Peter Bent Brigham Hospital at 8 15 p.m. Dr A Rosenbluth will speak on 'A Physiological Analysis of Abnormal Neuromuscular Function.'

SOUTH END MEDICAL CLUB

The next meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, January 21, at 12 m. Dr George Levene will speak on 'The Relation of Pituitary Function and Mental Development.'

Physicians are cordially invited to attend.

BOSTON DOCTORS
SYMPHONY ORCHESTRA

The Boston Doctors Symphony Orchestra will rehearse under Alexander Thiede, formerly concert master of the Cleveland Symphony Orchestra, every Thursday at 8 30 p.m. Those interested in becoming members should com-

municate with Dr Julius Lomay, Pelham Hall Hotel, Brookline (BEA 2430).

PETER BENT BRIGHAM HOSPITAL

There will be a seminar of the medical staff of the Peter Bent Brigham Hospital on Wednesday, January 8, in the students' laboratory of the hospital at 12 15 p.m.

FREE PUBLIC LECTURES

Harvard University has recently announced the subjects and speakers in its course of free public lectures on medical topics that are given each year at the Harvard Medical School. As usual these will be given in the amphitheater of Building D at 4:00 p.m. on Sundays. The schedule is as follows:

January 5. The Common Cold and How to Treat It. Dr. William B. Breed.
 January 12. Hormones in Children. Dr. Joseph C. Aub.
 January 19. How Accidents Happen. Dr. Henry C. Marble.
 January 26. Medical Aids to Justice. Dr. Alan R. Moritz.
 February 2. Modern Advances in Surgery. Dr. Oliver W. Cope.
 February 9. Medical Problems Presented by Selective Service. Dr. Frederick F. Russell.
 February 16. The Use and Abuse of Vitamins. Dr. Maurice B. Strauss.
 February 23. Fatigue and Health. Dr. David B. Dill.
 March 2. The Transfusion of Blood and Blood Banks. Dr. Carl W. Walter.
 March 9. The Pathway of Medical Discovery. Dr. Reginald Fitz.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, JANUARY 5

SUNDAY, JANUARY 5

†4 p.m. The Common Cold and How to Treat It. Dr. William B. Breed. Free public lecture. Harvard Medical School, Building D

†4 p.m. The Common Background of Many Symptoms. Dr. Arlie V. Bock. Public health lecture. Cambridge Hospital, Margaret Jewett Hall

MONDAY, JANUARY 6

12 15-1 15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater

TUESDAY, JANUARY 7

*9-10 a.m. Public Health in National Defense. Dr. H. D. Chope. Joseph H. Pratt Diagnostic Hospital

12 15-1 15 p.m. Clinicorontogenological conference. Peter Bent Brigham Hospital amphitheater

8 15 p.m. Some Recent Advances in the Endocrinology of the Female. Dr. Ephraim Shorr. Greater Boston Medical Society. Beth Israel Hospital, Boston

WEDNESDAY, JANUARY 8

*9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital

*12 m. Clinicopathological conference. Children's Hospital

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Psychotherapy Treatment that attempts to improve the condition of a human being by means of influences that are brought to bear upon his mind By Lewellys F. Barker, M.D., professor of medicine, emeritus, Johns Hopkins University School of Medicine, visiting physician, Johns Hopkins Hospital, Baltimore. 12°, cloth, 218 pp. New York D. Appleton Century Company, Incorporated, 1940 \$2.00

A Surgeon Explains to the Layman By M. Benmosché, M.D. 8°, cloth, 317 pp., with 62 illustrations. New York Simon and Schuster, 1940 \$3.00

Psychiatric Social Work By Louis Meredith French, director, Study of Trends, American Association of Psychiatric Social Workers, and psychiatric social worker and instructor in mental hygiene, New Jersey State Teachers College, Newark. 8°, cloth, 344 pp. New York The Commonwealth Fund, 1940 \$2.25

The 1940 Year Book of Pathology and Immunology, Pathology Edited by Howard T. Karsner, M.D., professor of pathology and director, Institute of Pathology, Western Reserve University, Cleveland. *Immunology* Edited by Sanford B. Hooker, M.D., professor of immunology, Boston University School of Medicine, member, Evans Memorial for Clinical Research and Preventive Medicine, and immunologist, Massachusetts Memorial Hospitals. 12°, cloth, 688 pp., with 113 illustrations. Chicago The Year Book Publishers, Inc., 1940 \$3.00

Compendium Phytaceae By Charles Morton. Compiled about 1680. Vol. xxxiii of the publications of The Colonial Society of Massachusetts. 8°, cloth, 237 pp. Boston The Colonial Society of Massachusetts, 1940 \$5.00

Man's Greatest Victory Over Tuberculosis By J. Arthur Myers, Ph.D., M.D., professor of medicine and preventive medicine and public health, University of Minnesota, and chief of medical staff, Lymanhurst Health Center, Minneapolis. 4°, cloth, 419 pp., with 31 illustrations. Springfield, Illinois Charles C. Thomas, 1940 \$5.00

Multiple Human Births Twins, triplets, quadruplets and quintuplets By Horatio Hackett Newman, Ph.D., Sc.D., professor of zoology, University of Chicago. 8°, cloth, 214 pp., with 24 illustrations. New York, Doubleday, Doran and Company, Incorporated \$2.50

The 1940 Year Book of Industrial and Orthopedic Surgery Edited by Charles F. Painter, M.D., orthopedic surgeon, Massachusetts Women's Hospital and Beth Israel Hospital, Boston. 12°, cloth, 484 pp., with 299 illustrations. Chicago The Year Book Publishers, Incorporated, 1940 \$3.00

The New International Clinics Original contributions, clinics and evaluated reviews of current advances in the medical arts Edited by George Morris Piersol, M.D., professor of medicine, University of Pennsylvania, Philadelphia. Volume IV, New Series 3, 1940. 8°, cloth, 326 pp., with 47 tables and 124 figures. Philadelphia J. B. Lippincott Company, 1940 \$3.00

A Family Doctor's Notebook By I. J. Wolf, M.D., professor of medicine, emeritus, University of Kansas School of Medicine. 8°, cloth, 315 pp. New York Fortuny's, 1940 \$2.00

Blood Pressure Study 1939 4°, cloth, 69 pp. New York compiled and published by The Actuarial Society of America and The Association of Life Insurance Medical Directors, 1940 \$4.00

BOOK REVIEWS

Operative Surgery Volumes I and II, fifth edition. By J. Shelton Horsley, M.D., LL.D., and Isaac A. Bigger, M.D. With contributions by C. C. Coleman, M.D., Austin I. Dodson, M.D., John S. Horsley, Jr., M.D., and Donald M. Faulkner, M.D. 4°, cloth, Volume I, 768 pp., with 802 illustrations, and Volume II, 1567 pp., with 1391 illustrations. St. Louis C. V. Mosby Company, 1940 \$18.00 (set)

The title might lead one to think that this set of two volumes deals only with specific operations. Actually, the word "operative," has been used in its broadest sense, and includes physiology, diagnosis, indications for surgery and many other considerations so essential in obtaining good results.

All the surgical specialties are included, and some of the chapters have been written by authorities in the field. The scope of the work precludes a thorough discussion of some surgical problems, but a good balance is maintained in the editing of all but a few sections. Although the subject has some interest to the surgeon, the space devoted to ligation of arteries seems excessive in view of the relatively infrequent application of this procedure.

The chapters by Dr. Horsley, Sr., deserve special mention. The history, the references to recent contributions and the reasons for a procedure are presented with unusual clarity by this careful student of surgery. His results in complications of acute appendicitis are difficult to improve, and bespeak excellent practical judgment.

These two volumes serve as useful reference for the general surgeon and for the study of surgery in the medical curriculum.

Physical Therapy for Nurses By Richard Kovacs, M.D. Second edition, thoroughly revised. 8°, cloth, 335 pp., with 99 illustrations. Philadelphia Lea & Febiger, 1940 \$3.25

This work is divided into seven parts: an introduction, "Heat," "Sunlight," "Electricity," "Water," "Massage," and "Exercise." These subjects are discussed from the standpoint of physics, physiological effects and technique of application. Although the author has had to be brief, and at times even dogmatic, his method of writing is fortunately such that he has managed to crowd into a small space a great deal of useful information. The tables, diagrams and photographic illustrations of apparatus and technique serve to clarify the text.

Although this book is intended for nurses and technicians who are expected ordinarily to carry out the treatments prescribed by the physician, it gives them, in addition to the technique of application, an insight into the motives or rationale for the employment of these therapeutic measures. It is a praiseworthy contribution to the furtherance of the education of nurses in physical therapy.

The New International Clinics. Original contributions: Clinics and evaluated reviews of current advances in the medical arts. Edited by George Morris Piersol, M.D. Vol. II, New Series 3, 1940. 8°, cloth, 365 pp., with 100 illustrations and 23 tables. Philadelphia: J. B. Lippincott Company, 1940. \$3.00.

This volume is a valuable addition to the series. There are original contributions that deal with varied subjects, among them fungous infections, intermittent claudication associated with sclerotic lesions of the abdominal aorta, theoretical and practical considerations of vitamin K, pelagra therapy and fusospirochetosis.

In clinics by members of the faculty of Rush Medical College and the University of Chicago, the applied physiology of the testis, the glandular treatment of male hypogonadism, malignant giant-cell tumors of the bones and many other interesting subjects are discussed.

The quality of *International Clinics* has long been demonstrated. This volume maintains the high standards of its predecessors.

An Introduction to Biochemistry. By William Robert Fearon, M.A., ScD., M.B., F.I.C. Second edition. 8°, cloth, 475 pp. St. Louis: C. V. Mosby Company, 1940. \$3.75.

In the last few years, a great many texts have appeared on the subject of biochemistry. The author of each has often contributed to different aspects of the problem. Dr. Fearon adds more detail to the subject of chemistry itself and to the chemistry of each of the important component chemical units that take part in biological systems. However, the book is weak in the linking of each of the metabolic processes, and it is extraordinarily brief in discussing the functions of chemical entities. The reader should be warned of numerous mistakes throughout the text. For example, gram instead of milligram has been written in the text, and in the discussion of phosphoflavins, co-carboxylase is discussed instead of co-deaminase. The structural formulas for the sex hormones are erroneous and should be changed. The section on acid-base balance is incomprehensible, because of omission rather than commission. On the whole, the book cannot be recommended as an ideal text for the subject.

Green's Manual of Pathology. Revised and enlarged by H. W. C. Vines, M.A., M.D. Sixteenth edition. 8°, cloth, 1166 pp., with 701 illustrations. Baltimore: Williams & Wilkins Company, 1940. \$8.50.

The sixteenth edition of *Green's Manual of Pathology* is divided into two parts, the first covering the general principles of pathology and the second concerned with the special pathology of organs in relation to clinical medicine. The chapters on bacteriology and parasitology have been omitted. Part I contains new chapters dealing with the process of repair of tissues and with the general character of tumors in the light of recent cancer research. In Part II the chapter on diseases of the blood and diseases of lymphatic tissue and the spleen has been replaced by a chapter on diseases of the reticuloendothelial system, in which the leukemias are included. There is also a chapter on the anemias.

Because pathology is not a static subject but reflects the continuous changes in the knowledge of diseases, factual material is often altered or augmented; an almost endless number of topics demand inclusion. As a textbook on

pathology this volume is very difficult to evaluate because many very important subjects are necessarily omitted.

The arrangement of the various chapters conforms with the standard works in pathology already published in this country. There is an excellent chapter on immunity, allergy and infections, and the one on diseases of the ductless glands is especially informative. The book contains many illustrations, although many show relatively low magnification. Unfortunately, there are no references to the literature, which is a serious omission, since practically all American books on pathology have a voluminous bibliography that is especially useful to the laboratory worker. Except for this omission, the book can be recommended to medical students, because it covers thoroughly the basic facts in the study of pathology.

Psychology and Psychotherapy. By William Brown, D.M. (Oxon.), D.Sc. (Lond.), F.R.C.P. Fourth edition. 8°, cloth, 260 pp. Baltimore: Williams & Wilkins Company, 1940. \$4.75.

The author states in the introductory chapter that he hopes this book "will provide the general reader not only with a grasp of the position and achievements of psychology and psychotherapy today—but also with a psychological basis for the study of politics and international relations." To fulfill this Herculean task, he begins with a presentation of some of the theories of Freud, Jung, Janet, Adler, Morton Prince and others, with the emphasis on Freud's concept of the unconscious and dreams. This portion of the book is followed by theories of the emotions and the author's experience in the treatment of psychoneurotic soldiers in World War I. The chief factors in his management of these cases consisted of persuasion, "whereby the patient was rationally convinced of the true nature of his symptoms," and hypnosis. Seventy per cent of the men returned to the line after an average of a fortnight's rest and treatment in the hospital. In view of such excellent results it is surprising to read later that the author let himself give "mental analysis to the utmost extent" and "suggestion treatment in the most vigorous form" to patients with Korsakow's syndrome due to alcohol. The poor results from psychotherapy in this group of cases were to be expected and might easily have fostered the author's mistaken notion that it is sufficient in a book on psychotherapy to enumerate the psychoses "and pass on, as they give little scope to psychotherapy."

The following are some of the titles of chapters in the latter half of the book: "Sublimation and Spirituality," "Suggestion," "Hypnotism and Faith" and the "Psychology of Peace and War." Here and there these chapters make interesting reading, but they contain little to recommend them to the physician seeking guidance with regard to clinical cases.

Atlas of Cardioroentgenology. By Hugo Roesler, M.D. F°, cloth, 124 pp., with 166 illustrations. Springfield, Illinois: Charles C Thomas, 1940. \$8.50.

This book is more than a good collection of typical x-ray pictures. It is the work of a teacher with a gift for graphic presentation of his material. The x-ray appearances are well correlated with clinical, electrocardiographic and anatomical findings. The printer has achieved remarkably sharp reproductions of the x-ray films. The atlas will not take the place of a comprehensive text or reference book, but it does offer a most lucid introduction to the subject.

SULFATHIAZOLE: A CLINICAL AND IN VITRO STUDY OF ITS USE IN INFECTIONS OF THE URINARY TRACT*

CHARLES H. RAMMELKAMP, M.D.,† AND LEWIS T. STONEBURNER, III, M.D.‡

BOSTON

IN the past decade there have been great advances in the treatment of infections of the urinary tract. Before the introduction of sulfanilamide, interest was centered primarily on methenamine and mandelic acid. These urinary antiseptics depended for their action on a certain degree of urinary acidity and the necessary concentration of the bactericidal substance in the urine, but such conditions were difficult to obtain in patients with acute infection, depressed renal function or obstructive lesions of the urinary tract. For these reasons, both drugs were of only limited value. With the introduction of sulfanilamide, reports began to appear concerning its use in urinary-tract infections. It has the advantage of being effective in either an alkaline or an acid urine, provided the concentration is adequate. From the published reports, there is no doubt that sulfanilamide is an effective agent in the treatment of many of these infections.¹⁻⁴ Because certain organisms respond slowly, if at all, to this drug, other chemotherapeutic agents were tested.

Fosbinder and Walter⁵ recently described several thiazole derivatives of sulfanilamide, the most promising of which appears to be sulfathiazole. Several papers⁶⁻⁸ have already appeared concerning in vitro studies of these compounds on organisms commonly associated with urinary-tract infections.

This report deals with the study of 25 patients with infections of the urinary tract due to *Escherichia coli*, *Proteus vulgaris* and *Staphylococcus aureus* who were treated with sulfathiazole; it also discusses comparative studies on the action of various sulfanilamide derivatives on these organ-

isms in vitro. The details of the cases are recorded in Table 1. There were 20 cases of infection due to *Esch. coli*, 3 due to *P. vulgaris* and 2 due to *Staph. aureus*. The primary diagnoses included cystitis, pyelonephritis and perinephritic abscess. The associated lesions included prostatic obstruction, renal stones, megaloureters, pyonephrosis, diabetes mellitus, vesicovaginal fistula, cord bladder and draining cystostomy wounds.

METHOD OF STUDY

To determine the effectiveness of sulfathiazole in the treatment of urinary-tract infections, the following procedures were carried out on each patient. Samples of urine were obtained from women by means of catheterization, and freshly voided specimens were obtained from men. Urine was collected for examination before treatment, two days following the institution of therapy, and at varying intervals thereafter. All cultures of the urine were made within thirty minutes after it was obtained or voided. The organisms were isolated, identified and stored on agar slants. In the specimens of urine containing sulfathiazole, 1 cc. of urine was added immediately to 10 cc. of broth, since the bacteria were soon killed if the urine was allowed to stand. Bacterial counts on urinary sediment were recorded in number of cells per high-power field on both centrifuged and uncentrifuged specimens. The free and total sulfathiazole was determined in the blood and urine after two days' treatment, and at varying periods thereafter. The majority of patients received 2 gm. of sulfathiazole§ by mouth at the beginning of the treatment, followed by 1 gm. every four hours, although some received smaller doses. The total duration of the treatment varied from four to twenty days. The amount of free sulfathiazole

*The numbers indicate the hospital days on which the cultures were taken.

in the blood varied from 0.8 to 9.7 mg. per 100 cc., and the concentration in the urine varied from 32 to 456 mg. per 100 cc.

In vitro studies were carried out, using as culture mediums the urine obtained before therapy and after two days of treatment. After the pH of these two samples had been adjusted to 6.5 or 7.0, they were passed through a Berkefeld filter and stored in an icebox until used. One cubic centimeter of a saline dilution of a twelve-hour broth culture of the organism originally isolated from the same patient was added to 10 cc. of the two samples of urine. The tubes were then incubated at 37°C., pour plates were made from the culture at four, eight, twelve and twenty-four hours, and the colonies were counted. Each experiment was set up so that a small inoculum of 10 to 100 organisms per cubic centimeter and a large inoculum of 1000 to 100,000 organisms per cubic centimeter were used.

RESULTS OF CLINICAL STUDY

Escherichia coli Infections

Of 20 cases of *Esch. coli* infection 13 were cured, 5 were improved, and in 2 the treatment failed to

FIGURE 1. Pyelitis, with Bacteremia (Case 1).

influence appreciably the course of the disease. All the uncomplicated cases made a dramatic clinical recovery, with disappearance of symptoms and a fall of temperature to normal within two to four days. In 2 (Cases 9 and 17) the cultures remained positive but relapses did not occur during the ensuing month.

The details of Case 1 are shown in Figure 1; they are illustrative of the response seen in the cases classified as cured. This fifty-six-year-old woman entered with a history of dysuria of three weeks' duration. On admission she had a chill, *Esch. coli* was recovered from the blood and urine, and there was pyuria. The response to sulfathiazole therapy was dramatic, and subjective improvement was noted within twenty-four hours. Figure 2A shows the marked bactericidal effect of this patient's urine, during therapy, for the organism isolated before the onset of treatment. Here 10,000 organisms per cubic centimeter of urine were killed within twenty-four hours, whereas the organisms grew freely in the urine containing no sulfathiazole. This is the type of growth curve obtained for the majority of the patients with *Esch. coli* infections when the urine is studied before and during treatment with sulfathiazole.

The 5 cases classified as improved had the following complications. In Case 6 the patient had diabetes as well as chronic pyelonephritis. Sulfathiazole had to be discontinued after four days because of nausea and vomiting. Although the symptoms of infection were relieved and the urine became sterile, the patient continued to run a low-grade fever. In Case 11 the patient, who also had a severe diabetes, was apparently cured but relapsed after therapy was discontinued, and on readministration of sulfathiazole developed fever and a cutaneous reaction. In Case 20 there was a relapse after five days of treatment but the patient responded promptly to a second course. Initially the patient was probably insufficiently treated. In Case 20 there was a prostatic obstruction and an indwelling catheter was used. The cultures became sterile and fever subsided, but pyuria continued. In Case 18 a sixty-year-old man had a large, palpable, nonfunctioning left kidney; the urine became clear and sterile and dysuria was relieved, but the low-grade fever continued.

Two cases were classified as failures. In one (Case 2) there was a calculus in the left ureter, and under treatment the patient continued to show fever and bacteremia. In the other (Case 5) the patient developed shock and died following a genitourinary procedure.

Proteus vulgaris Infections

There were 3 cases of *P. vulgaris* infection, 2 of which showed an immediate favorable response following the use of the drug (see below). The third (Case 23) was seen following a one-stage prostatectomy; the patient had not only suprapubic drainage of the bladder but also multiple lung abscesses. *P. vulgaris* was isolated in almost pure culture from both the urine and the sputum.

While the patient was receiving sulfathiazole, the urine cultures became negative and there was clinical improvement. The drug treatment was discontinued when the patient left our care, and *P. vulgaris* promptly reappeared in the urine draining from the suprapubic wound.

Figure 3 illustrates the clinical course of a sixteen-year-old girl (Case 25) who was seen at the Evans Memorial Hospital. On entry she was found to have an atonic bladder, flaccid paralysis of the left

after treatment was started. Here, with an original inoculum even as large as 100,000 organisms per cubic centimeter there was marked bacteriostasis. The concentration of free sulfathiazole was 222 mg. per 100 cc. of urine.

The other patient (Case 24), whose case was especially interesting because of a long history of infection and recovery after small doses of sulfathiazole, was followed through the courtesy of Dr. Maurice Strauss. She was seventy years old, and

FIGURE 2. Growth Curve of *Escherichia* (*Bacillus*) *coli* in Urine (Case 1).

S.T. = sulfathiazole; M.T. = sulfamethylthiazole; S.P. = sulfapyridine; P.A.B.S. = sulfanilamide.

arm and leg, flaccid paresis of the right leg and a left-sided Horner's syndrome. An etiologic diagnosis could not be definitely established, but there was thought to be a widespread vascular lesion of the spinal cord. The patient was placed on tidal drainage of the bladder for forty-four days, after which she regained normal function of the bladder. She had some dysuria and occasional bouts of low-grade fever. Eleven specimens of urine were positive for *P. vulgaris* and contained many leukocytes. She was given two courses of sulfanilamide, without apparent benefit. Two days after the beginning of sulfathiazole therapy the urine was sterilized, and it remained sterile. Figure 4 A demonstrates the results of the in vitro action of this patient's urine collected before and two days

had a vesicovaginal fistula, and a *P. vulgaris* infection of the bladder of six months' duration. The symptoms were due to spasm and local irritation of the bladder. She was given 0.5 gm. three times daily. Examination at the end of seven days showed that all local signs of irritation had disappeared and that symptoms were relieved for the first time in many months. The urine culture became negative for *P. vulgaris*.

Staphylococcus aureus Infections

Two cases of *Staph. aureus* infection of the urinary tract were treated. In Case 21 the urine became sterile under therapy; the fever persisted, however, and the patient developed signs of perinephritic abscess. Drainage at operation was fol-

lowed by complete recovery. The course was uninfluenced in Case 22. As can be seen from the table, the patient had pyonephrosis, megaloureters and a lung abscess. Both cases demonstrate the fact that if response to drug therapy is not obtained some complicating factor is usually present. That the urine becomes bactericidal is clearly dem

shows a typical example of one of the growth curves. In both the control and the drug-containing tubes there was an initial growth period of about four hours, following which the effect of the various drugs became manifest. The urine containing sulfanilamide showed moderate bacteriostasis, but that containing sulfapyridine showed it to a more

FIGURE 3 Cystitis Due to *Proteus vulgaris* (Case 25)

onstrated in Figure 5A (Case 21). The urine showed complete sterilization at the end of twenty four hours' incubation.

COMPARATIVE STUDY OF SULFANILAMIDE DERIVATIVES IN URINE

To justify a report on the use of a new drug, namely, sulfathiazole, it was believed that a comparative study of the sulfanilamide derivatives in vitro was necessary. The experiments reported here were all done on the same sample of urine, which had been adjusted to a pH of 7.0. Sulfanilamide, sulfapyridine, sulfamethylthiazole* and sulfathiazole were added, so that the final concentration was 10 mg per 100 cc. Growth curves were then determined following a technic similar to that described above.

Various strains of *Esch. coli* that had recently been isolated from patients with urinary tract infections were used in these experiments. Figure 6A

marked degree. Urines containing sulfathiazole and sulfamethylthiazole both exhibited bactericidal as well as bacteriostatic action. Usually sulfathiazole was a little more effective than sulfamethylthiazole, however, the difference was not striking.

Occasionally some strains of *Esch. coli* appeared to be somewhat more resistant to the action of these drugs. Figure 2B is an example. Here, although the original inoculum was larger than that in Figure 6A, the action was not so marked as that generally observed. However, urine containing sulfathiazole again showed the most marked bacteriostasis. Not infrequently, *Aerobacter aerogenes* is found to be the infecting organism in urinary tract infections. Figure 6B shows the comparative action of the drugs on this organism, which had recently been isolated from the blood stream of a patient with urinary tract infection. In this experiment the action of sulfathiazole was striking.

Sulfanilamide therapy in *P. vulgaris* infections of

FIGURE 4. Growth Curve of *Proteus vulgaris* (B. proteus) in Urine (Case 25).

FIGURE 5. Growth Curve of *Staphylococcus aureus* in Urine (Case 21).

the urinary tract has been somewhat disappointing, and the results of a comparative study of the activity of the drugs against this organism are therefore especially interesting. Long and Bliss⁷ reported some inhibition of growth in broth cultures containing 10 mg. per 100 cc. Figure 4 B is an example of the action of sulfathiazole on *P. vulgaris* in urine. When large inoculums were used all tubes showed growth, but some bacteriostatic action could be demonstrated in those con-

and sulfamethylthiazole. With a larger inoculum there was bacteriostasis without complete sterilization at the end of twenty-four hours' incubation. Sulfathiazole appeared to be the most effective of the four drugs used against *Staph. aureus*.

DISCUSSION

Sulfathiazole therapy for urinary-tract infections due to *Esch. coli* and *P. vulgaris* has given encouraging results. In this clinical study it has been

FIGURE 6. Growth Curves of *Escherichia coli* (A) and *Aerobacter aerogenes* (B) in Urine.

taining sulfathiazole. Sulfanilamide in this experiment, as well as in others not here reported, had little demonstrable effect. Sulfapyridine appeared to be more effective than sulfanilamide, and sulfathiazole and sulfamethylthiazole the most active of all.

Sulfanilamide and sulfapyridine have been disappointing in the treatment of all staphylococcal infections. Therefore, a drug that is effective against this organism would indeed be most useful. Rammelkamp and Keefer⁹ have shown that in whole defibrinated blood sulfathiazole is an effective bactericidal and bacteriostatic agent, even more so than sulfamethylthiazole, sulfapyridine or sulfanilamide. This was also found to be true when urine was used as the medium (Fig. 5 B). When a small inoculum was used there was complete sterilization of the urine containing sulfathiazole

demonstrated that usually the urine not only becomes sterile and free of leukocytes, but also exhibits definite bacteriostatic and bactericidal action against twenty strains of *Esch. coli*, three strains of *P. vulgaris* and two strains of *Staph. aureus*.

This bacteriostatic and bactericidal action of sulfathiazole was demonstrated in urine containing between 32 and 456 mg. of free sulfathiazole per 100 cc. A favorable response was obtained in three patients (Cases 15, 16 and 17) with a concentration of less than 50 mg. per 100 cc. It appears from these clinical studies and also from studies in vitro that a concentration of between 50 and 200 mg. per 100 cc. of free sulfathiazole is sufficient to sterilize the urine. It is necessary to give 2 to 4 gm. of sulfathiazole in divided doses daily to obtain such concentrations. Restriction of fluid is not neces-

sary. In severe infections, especially those associated with stasis of urine, a concentration of sulfathiazole between 200 and 450 mg. is needed. This amount of the drug in the urine may be obtained by giving 4 to 6 gm. in divided doses daily.

No severe toxic manifestations were encountered in these cases. Nausea and vomiting occurred in two cases, and there were febrile reactions in 3, one accompanied by a cutaneous eruption. The bloods and urines were followed closely, but no evidence of toxic effects was noted.

It is interesting that complicating factors, such as diabetes mellitus, prostatic obstruction, pyonephrosis and nausea and vomiting, were present in the patients not promptly cured. Close analysis shows that some improvement took place under drug therapy, and this treatment seems valuable even in these cases.

In vitro studies on the action of the various sulfonamide compounds in concentrations of 10 mg. per 100 cc. showed that sulfathiazole had the most marked bacteriostatic and bactericidal action. Several experiments with higher concentrations of the drugs showed sulfathiazole to be more effective, even at these concentrations.

CONCLUSIONS

Sulfathiazole was used in the treatment of 25 cases of urinary-tract infections, and it was shown

to be effective against *Escherichia coli*, *Proteus vulgaris* and *Staphylococcus aureus* infections.

The urine of patients receiving sulfathiazole exhibited marked bactericidal and bacteriostatic action in vitro.

Comparative studies of the action of sulfathiazole, sulfamethylthiazole, sulfapyridine and sulfanilamide in urine containing 10 mg. per 100 cc. showed that sulfathiazole is the most effective bactericidal and bacteriostatic agent against *Esch. coli*, *Aerobacter aerogenes*, *P. vulgaris* and *Staph. aureus*.

Sulfathiazole deserves further clinical trial in the treatment of urinary-tract infections.

FAMILIAL HEMOLYTIC CRISIS*

Report of Three Cases Occurring Within Ten Days

WILLIAM DAMESHEK, M.D.†

BOSTON

WITHIN a period of ten days, three children in the same household—two brothers and a cousin—became successively ill and were admitted to the Waltham Hospital for treatment. Each child was found to be suffering from a severe hemolytic crisis, and splenectomies were performed on all three. The first child died, but the other two made uneventful recoveries. This report is presented because hemolytic crises occurring successively at short intervals in members of the same family are rare, and because the management of these cases is of the utmost importance.

*From the Waltham Hospital, the Joseph H. Pratt Diagnostic Hospital, and the Blood Clinic, Boston Dispensary. Aided by a grant from the Charlton Fund, Tufts College Medical School.

†Consultant in hematology, Waltham Hospital and the Joseph H. Pratt Diagnostic Hospital, chief, Blood Clinic, Boston Dispensary.

CASE REPORTS

FAMILY BACKGROUND. The patients, D. C. M., 2nd, R. M., Jr., and M. McN., were grandchildren of D. C. M. aged 70, a known case of congenital hemolytic icterus, who considered himself to be in good health, was able to do his daily work as a carpenter and had no symptoms. He had never been anemic and had never been subject to sudden attacks of icterus. Examination revealed slight icterus and a large spleen extending three fingerbreadths below the left costal margin. Examination of the blood (Table 1) showed no definite anemia, although reticulocytosis, spherocytosis and increased hypotonic fragility were present. His son, R. M., aged 41, the father of D. C., 2nd, and of R. M., Jr., had been jaundiced since childhood. He was troubled with lack of "pep," occasional spells of vomiting and sporadic attacks of marked jaundice. Examination revealed moderate icterus and an enlarged spleen felt four fingerbreadths below the left costal mar-

gin Examination of the blood (Table 1) showed high hemoglobin levels and no anemia, although reticulocytosis, spherocytosis and increased hypotonic fragility were present. R M had three brothers and a sister. One brother had tuberculosis, the others were well. One sister, who died at 26 of miliary tuberculosis, had been jaundiced for years. Her only child, M McN, lived with the R M family, having been adopted by them. There were prob-

margin Examination of the blood showed a red-cell count of 1,250,000, with 36 per cent hemoglobin (Sghli), and a white-cell count of 3800. The red cells showed an extreme degree of spherocytosis, and the average red cell diameter was 5.63 microns. On April 16, the patient's condition was critical, the red cell count having dropped to 1,010,000. An emergency splenectomy was decided on just prior to operation the patient was given 1000 cc of

ably other cases of hemolytic icterus in the family, which was a large one, but this could not be verified.

CASE 1 D C M, 2nd, an 11 year-old boy, had been known to have jaundice, anemia and splenomegaly for years. About three times a year he developed slight attacks of fever, weakness, pallor and increased icterus, but the attacks were always mild and cleared up after a few days' rest at home. On April 13, 1938, he complained of dizziness and pain in the midabdomen and vomited several times. He became rapidly worse on April 14, when

normal salt solution and 500 cc of citrated blood. The operation was performed by Dr. H. Quimby Gallupe with out incident. During the operation 600 cc of blood was given slowly intravenously. In all, 2100 cc of fluid was given intravenously within 90 minutes. At the end of the operation the patient began to pass large quantities of frothy sputum. All attempts at resuscitation failed, and the patient shortly expired, apparently of pulmonary edema. Permission for autopsy was refused.

CASE 2 R M, Jr, a 12 year-old boy, like his brother

well marked jaundice and pallor were noted. The next day his condition seemed desperate and he was admitted to the Waltham Hospital by Dr. Frank J. Fleming, to whom I am indebted for the privilege of seeing these cases.

Physical examination revealed a small, rather under developed boy lying quietly in bed. He appeared acutely ill, had the appearance of mild shock, and showed well marked pallor, with a lemon yellow discoloration of the skin and sclera. The temperature ranged between 101 and 103.5°F, and the pulse rate between 120 and 140. A soft systolic murmur was heard at the apex. The spleen was palpable three fingerbreadths below the left costal

(Case 1), had been known to have hemolytic icterus for years. Several times annually he had mild attacks of fever and malaise, during which an increase in pallor and jaundice was always noted. The present attack, which was much severer than any previous one, began on April 21, 1938, or 8 days after the onset of his brother's crisis. It was characterized by fever, malaise, headache and left sided abdominal pain. The next day there was marked dizziness and weakness, and the patient was admitted to the Waltham Hospital.

Physical examination revealed an acutely ill child, somewhat small for his age, with extreme pallor and slight

jaundice. The temperature was 103.6°F., the pulse 120, and the blood pressure 104/60. The heart was not enlarged, but a rather loud, blowing systolic murmur was heard over the precordium. A large, somewhat tender spleen was felt three fingerbreadths below the left costal margin. Examination of the blood showed a marked anemia: a red-cell count of 1,220,000, with 30 per cent hemoglobin (Sahli), and an associated leukopenia (Table 2). There was extreme spherocytosis of the red cells, and the hypotonic fragility test showed beginning hemolysis at 0.64 per cent of sodium chloride solution, complete at 0.34 per cent. Because of the fatal result in Case 1, it was decided to give several transfusions prior to splenectomy, but spaced at intervals of at least 3 hours. Transfusions of citrated blood of 400 or 500 cc. each were accordingly given at 1, 4 and 10 a.m., April 23, with the result that at 3 p.m. the hemoglobin had risen to 70 per cent and the erythrocyte count to 3,330,000. On the

malaise and fever. The next day the patient complained of lower abdominal pain and headache, and on April 24 she was admitted to the Waltham Hospital.

Physical examination revealed a very delicate-looking, acutely ill child with marked pallor and slight icterus. The temperature was 103°F. and the pulse 120. The splenic edge was felt one fingerbreadth below the left costal margin. Examination of the blood showed a red-cell count of 1,700,000, with 35 per cent hemoglobin, and a white-cell count of 5000 (Table 3). There was marked spherocytosis, and the hypotonic fragility test showed beginning hemolysis at 0.80 per cent, with complete hemolysis at 0.56 per cent. Because the patient did not appear so severely ill as her cousins, it was decided to temporize for a day or two. During this period swine serum, prepared by the method recommended by Josephs,¹ was given in increasing dosage for its possible antihemolytic effect. However, by April 26 there was a slight though

morning of April 24 the patient looked considerably better, and there was a definite diminution in both the temperature and the pulse rate. However, the hemolytic process was apparently still quite active, as indicated by a drop in the erythrocyte count to 2,560,000 in 15 hours. Splenectomy was performed by Dr. Gallupe under nitrous oxide, oxygen and ether anesthesia, and 2 hours later another transfusion of 500 cc. of citrated blood was given. Sections of the spleen showed marked congestion of the pulp. On the following day, dramatic rises in both hemoglobin and red-cell count were evident. Convalescence was uneventful, the temperature and pulse becoming normal by lysis in 8 days. No further transfusions were necessary. At discharge from the hospital on May 6 the hemoglobin was 98 per cent and the red-cell count 4,640,000 (Table 2). The patient has since been entirely well and has shown a striking increase in weight and stature.

CASE 3. M. McN., a 5-year-old girl and the cousin of the two boys (Cases 1 and 2), had also been known to have hemolytic jaundice and had had several attacks of hemolytic crisis. The present attack began on April 22, 1938, the day after the onset in Case 2. There was at first

definite drop in both the hemoglobin level and the red-cell count. Transfusions of citrated blood in 300-cc. amounts were accordingly given on April 26 and 27, and a splenectomy was performed on the latter date by Dr. Gallupe. The spleen weighed 350 gm., and microscopic sections showed marked congestion of the pulp. Convalescence was uneventful. On May 4, the day of discharge, the red-blood cell count was 4,570,000 with 93 per cent hemoglobin, and the white-cell count 10,200. In the course of the next several months there was a definite increase in the diameter of the red cells and a great diminution in spherocytosis but a persistence of abnormal fragility. In April, 1940, spherocytosis was again definitely increased.

DISCUSSION

The Hemolytic Crisis

Congenital hemolytic jaundice is a chronic hereditary disease subject to more or less frequent and violent fluctuations in the degree of anemia and icterus, known as hemolytic crises. Most authorities²⁻⁴ consider the disease to be a hereditary dis-

order of red-cell formation in the bone marrow, with the production of small thick erythrocytes (spherocytes) as the salient feature:

The hemolytic crisis is difficult to explain on the basis of a congenital disturbance in blood formation. Its outstanding feature is the great increase in spherocytosis and blood destruction, features that closely resemble the sudden development of unusual hemolysis through the action of various toxic, chemical or immunologic substances. Dameshek and Schwartz⁵ showed that all the features of the hemolytic crisis, including the marked spherocytosis and increased fragility, could be imitated in the experimental animal by the injection of hemolytic heterophilic serum. These data indicated that spherocytosis is not necessarily of hereditary origin but may be induced by hemolysins of various types. Furthermore, a group of cases of acquired hemolytic icterus was observed in some of which hemolysins were found in the serum and in which spherocytosis and increased fragility were temporarily present.^{6,7} These cases, which indicated the close relation between the presence of hemolysins, hemolytic anemia and spherocytosis, also established from the clinical standpoint that spherocytosis was not necessarily of congenital origin. The concept was therefore advanced that hemolytic anemia or icterus was caused, not by an intrinsic defect of the marrow, but rather by the action of hemolysins of various types and in varying "doses" on mature red blood cells. Both the crisis of chronic congenital hemolytic jaundice and the sudden appearance of acute hemolytic anemia in a previously healthy person might be explained by a sudden increase in circulating hemolysins (arising from the spleen?), with the resultant development in the mature red cells of spherocytosis and increased fragility. The occurrence of hemolytic crisis in three members of the same household within a period of ten days might be further evidence in favor of an extrinsic rather than an intrinsic cause of the crisis.

The nature of the possible extrinsic cause in the reported cases was not determined. The possibility of an infectious process was thoroughly investigated. None of the children showed any evidence of an infection, although this does not exclude such a possibility. The fever present in each case is common to all severe hemolytic processes, and is therefore not necessarily infectious in origin. There was no evidence of an infectious process in any of the immediate family, nor was there any unusual incidence of "grippe" or some similar condition in the neighborhood. Except for their greater severity the crises were closely similar to previous ones, which, according to the mother, always oc-

curred in the spring or fall. The possibility that the children might be allergic to grasses or ragweed was thereupon investigated, but negative results were obtained. The grounds about the house were searched for plants such as the fava bean, but none were found. No unusual foods had been eaten.

In each case, the blood serum and the splenic-vein blood (at splenectomy) were examined for iso-hemolysins, according to the technic described by Dameshek and Schwartz.⁵ None were found, and no unusual agglutinins of either the so-called "cold" or "auto" type were discovered. Severe transfusion reactions did not occur, and no hemolytic or agglutination reactions were observed in cross-matching the patient's blood serum with various donor red cells.

The only comparable group of cases of hemolytic crisis in the literature is that of Dedichen,⁸ reported in 1937. Under the title of "Holla Disease": Epidemic appearance of anemic crisis in hemolytic icterus," this author reported a strange disease that had successively attacked most of the members of two families living in or near Holla, Norway. In the first family (H.), 4 of the 7 children had been taken ill in November, 1933, with fever, vomiting, pallor and enlargement of the spleen. Nine members of the second family (S.), including the father, successively developed acute hemolytic crises in February and March, 1934. The dates of onset were February 22 and March 1, 6, 8, 10, 14, 17, 19 and 22. The hemoglobin readings varied from 20 to 40 per cent, and the hypotonic fragility was greatly increased in all. There were 2 deaths, one in a nine-year-old child (untreated) and the other in a twenty-year-old girl, apparently because of a transfusion reaction (incorrect typing?). Three patients recovered spontaneously, and 4 recovered after one or two transfusions. The typical features of congenital hemolytic jaundice persisted in all the cases, although the splenic size greatly diminished.

Dedichen believed that the hemolytic crises were probably induced by an infection of the "grippal" type, because one of the children of the S. family, not afflicted with the disease congenital hemolytic icterus, fell ill with typical "grippe" during the same period and did not develop anemia or splenomegaly. This opinion seems logical, especially in view of the large number of persons affected and the successive development of the crises within two to seven days of each other. Blood cultures and tests for serum hemolysins were not performed.

The reduction in leukocytes, thrombocytes and reticulocytes in the cases reported here appears at

first glance somewhat unusual, since in the presence of an acute hemolytic process one would expect to find the evidences of increased regenerative activity on the part of the bone-marrow, that is, leukocytosis, thrombocytosis and reticulocytosis. The lack of these features might conceivably be due to unusual splenic activity. The spleen and the bone marrow may be said to have an antagonistic or reciprocal relation. One may speculate as to whether this relation is due to a hormonal influence of the spleen on the marrow, with the result that the maturation or delivery of cells to the circulation becomes inhibited. In sudden splenic hyperactivity, which Heilmeyer⁹ believes is at the basis of the hemolytic crisis, it is possible that the bone marrow may become inhibited, with resultant leukopenia, thrombocytopenia and reticulocytopenia. It is also possible that an obscure ("grippal" or influenzal) infection might somehow activate the spleen in these cases, with the resultant development of a hemolytic crisis.

Treatment of Hemolytic Crisis

From the experience gained both in these and in other cases, it appears that although emergency splenectomy as a therapeutic procedure is occasionally necessitated (Doan et al.¹⁰), the importance of placing the patient in proper condition for the operation is of primary concern. For the patient in apparent shock with fever and profound anemia, it is essential to replace fluids, electrolytes and blood. This may best be done by transfusions, preferably given slowly and at intervals sufficiently spaced to prevent undue strain on the circulation and the right side of the heart. Two to four transfusions of 500 cc. for an adult, or of 250 to 300 cc. for a child, given at three-hour to six-hour intervals are generally sufficient to obtain a quieter, healthier, less anemic patient, with a circulation that is better able to withstand the strain of splenectomy. The sudden introduction into the circulation of large quantities of fluids and blood preliminary to immediate operation (Case 1) may be distinctly harmful. It is therefore recommended that the immediate emergency be combated by transfusions properly spaced, with or without added parenteral fluids, to be followed by splenectomy within twelve to forty-eight hours, when the patient is relatively afebrile, less anemic and with a slower pulse.

Each hemolytic crisis undoubtedly puts a severe strain on the circulation and is usually followed by a prolonged convalescence. Children having frequent crises are generally underdeveloped. The

possibility is present, too, that a crisis may be so fulminating as to result in death or in the necessity for an emergency splenectomy. In a very severe crisis, as in the present cases, the operation of splenectomy is probably best not set aside, since the hemolytic tendency may continue to manifest itself as soon as the effects of transfusions have worn off. For these reasons, any child with congenital hemolytic jaundice who is subject to crisis should have a splenectomy performed, preferably between crises. In the presence of a very severe crisis, it is necessary to operate as soon as the patient has been placed in reasonably good condition by carefully spaced transfusions.

Finally a word about the operation of splenectomy is essential. This operation requires a fundamental knowledge of anatomy, skillful surgery and, at times, speed. Certain surgeons appear to possess the knack of delivering the spleen into the operative wound, clamping the splenic pedicle properly and performing the splenectomy—all with a minimum of trauma and wasted motion. In the very serious situation of emergency splenectomy, it is recommended that a surgeon be selected who has had experience in the technic of the operative procedure, and who is known for his adeptness in handling abdominal tissues.

SUMMARY

The appearance in quick succession of three cases of severe hemolytic crisis in one family necessitated emergency splenectomy in all three. Various clinical and hematological features suggested that the hemolytic crises developed because of some alteration outside the bone marrow, perhaps as the result of splenic activation. The operation of emergency splenectomy requires careful pre-operative and operative management.

REMOVAL OF OVER 1300 FOREIGN BODIES FROM A STOMACH*

PHILIP H. WHEELER, M.D.†

BRATTLEBORO, VERMONT

FOREIGN bodies in the stomach have received attention in the literature for a great many years. This case is reported because, in addition to the interest of an unusual collection of foreign bodies, it presents several unique features.

I have not been able to find in the literature any case on which three gastrotomies have been per-

ous objects than those in the case reported below. Other cases have been reviewed by Thorek.⁷

CASE REPORT

B. T., a 43-year old former railroad telegrapher, was a mental patient at the Brattleboro Retreat, where he had been committed for the second time, with a diagnosis of manic depressive psychosis, depressive phase. For several months he had been vomiting occasionally, with increasing frequency. There was coffee-grounds vomitus, with the occasional appearance of bright-red blood. The stools were tarry. Careful observation of the patient led the attendants to believe that he was swallowing foreign bodies. X-ray examination on October 10, 1933, at the Brattleboro Memorial Hospital revealed a large, irregular, opaque mass in the cardiac region of the stomach, measuring about 8 by 10 cm., that appeared to be made up of metal, including staples, tacks and wire. Staples and tacks were visualized in the colon on the right side of the abdomen, some of which appeared in the stools following catharsis. On October 19 x ray films showed the gastric mass still present and, in addition, 2 small pieces of metal in the ileum and a short piece of wire in the rectum. The patient was referred for immediate operative treatment, since the vomiting and gastric pain persisted and the general physical condition was becoming steadily poorer.

The patient was very anxious for relief and, contrary to his early denials, freely told of the foreign bodies he had swallowed during a period of 3 or 4 months. Before operation he prepared a partial list of these objects so that they "might not be overlooked." He had covered many of the objects, such as razor blades, needles, pins and glass, with chewing gum or food. He said that, in spite of these precautions, his throat had become very sore at times. He admitted that he had intended to commit suicide, but death in this manner became so uncomfortable that he changed to become a very co-operative patient.

Physical examination showed a moderately emaciated and pale, neurotic patient in some distress from epigastric pain. There was tenderness to pressure in the epigastrium. Other physical findings were normal.

Gastrotomy performed on October 20 revealed a large stomach, with the omentum adherent to the lower third of the lesser curvature. The stomach was opened through a transverse incision opposite this point. Numerous intermingled foreign bodies were removed with forceps and fingers. The entire gastric mucosa, especially that along the lesser curvature, was badly lacerated and friable. The omentum, adherent to the lesser curvature, covered the bed of an ulcer, 4.5 by 3.2 cm., that had eroded through the gastric wall. The tissue immediately surrounding the ulcer was extremely friable. The original gastric incision was extended to permit resection of the ulcer. Closure was made, leaving a drain in the lesser omental cavity because of the friable gastric wall. The pathological report was gastric ulcer.

Classification of the foreign bodies removed showed 69 narrow staples, 24 wide staples, 21 pieces of glass, 1 pen-

FIGURE 1. X-Ray Film Taken before the Second Operation.

formed, although Matthews¹ and Cannaday² have each reported a patient who underwent two. Other unusual features of this case are the great variety of sharp metallic foreign bodies and the large amount of broken glass ingested without acute perforation of the stomach or the intestines. The third unusual feature, the presence of an enormous benign ulcer that had eroded through the gastric wall, has been noted in a previous report.³ Chalk and Foucar,⁴ Gaylord⁵ and Wardell⁶ are among the few who have recorded a recovery following the removal of heavier or more numer-

*Presented at the annual meeting of the New England Surgical Society, Poland Spring, Maine, September 28, 1940.

†Assistant surgeon, Brattleboro Memorial Hospital.

cil lead, 72 miscellaneous metallic foreign bodies, including open safety pins, hairpins, corroded needles, pins, tacks, pieces of safety razor blade, a piece of hacksaw blade and a screw. The total of 187 foreign bodies weighed 97 gm. In addition, 2 small nails, 2 staples and

rence of pain typical of gastric ulceration. He denied having ingested additional foreign bodies. A modified Sippy regime was ineffective. The patient was suffering severely and was losing weight and strength. At this time he was despondent and attempted suicide. As a last

FIGURE 2. Foreign Bodies Removed at the Second Operation.

2 pieces of glass in the intestines were later delivered by enemas.

A gastric fistula opened through the drainage on the 7th postoperative day and closed spontaneously on the

FIGURE 3. X-Ray Film Taken before the Third Operation.

20th postoperative day; it never gave further trouble. The remainder of the wound healed by first intention. The early convalescence was stormy.

The patient was discharged to the Brattleboro Retreat on his 25th postoperative day. Soon he suffered recur-

resort he was placed on a course of Synodal. Coincident with the last treatment, he became free of pain and began to gain weight.

Up to 1938 the patient remained in good health and was free of pain. He took advantage of the liberty given him, with the result that, in July, 1938, 5 years after the first operation, he again complained of pain, had tarry stools, occasionally vomited and admitted having taken foreign bodies. X-ray examination showed opaque bodies in the stomach (Fig. 1). On July 15, a second gastrotomy through a 15-cm. incision of the anterior wall of the stomach revealed a mass of broken glass and a tangle of sharp pointed metallic bodies, surrounded by a semiclear, blackish fluid. The strong odor of the action of hydrochloric acid on iron was very evident. A handful of glass was removed at one time from the cardiac portion of the stomach. Many foreign bodies, including open safety pins, had to be untangled and removed individually. In the distal end of the stomach there was an ulcer large enough to admit the tip of a finger. This had a gray base, had not eroded through the gastric wall and was not disturbed. The gastric mucosa, except for one small area, was in good condition, in marked contrast to its friable condition 5 years previously. Perhaps the absence of razor blades accounted for this. The convalescence was uneventful. Complete laboratory studies were not available at this time, but a gastric analysis after operation showed tremendously high levels of acidity: free hydrochloric acid, 280 units; total acidity, 400 units.

Examination of the material removed showed over 440 pieces of glass and 277 metallic bodies, including wire, pins, needles, open safety pins, nails, a bottle cap and a few fragments from a barbed-wire fence, probably collected on his parole home to the farm. For some reason the patient had not swallowed razor blades this time. The weight of the foreign bodies was 551 gm.

Following the second operation the patient was given less liberty, in spite of which, during the following year, he was found to be ingesting other articles. He complained of some stomach distress, and x-ray films were ordered. These showed more foreign bodies (Fig. 3). Physically the patient was in excellent condition. The only abnormality was a fullness of the left midabdomen, which

gave forth metallic sounds on palpation. On May 4, 1939, the patient was again operated on in the surgical department of the Brattleboro Retreat, under Avertin anesthesia. An upper left rectus incision was used. Adhesions about the stomach were extensive. The mucosa showed little evidence of injury and was not friable. There was a small ulcer near the pylorus, which was not disturbed. A section of the gastric wall removed at this time was examined by Dr Arthur Wright, of Albany, New York, who reported as follows:

The mucosa is focally hemorrhagic and subcutely inflamed. The submucosa is diffusely hemorrhagic,

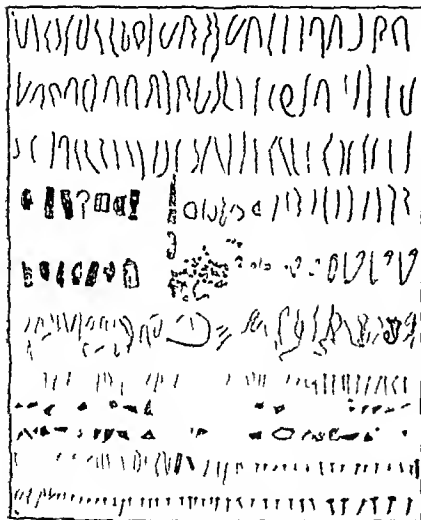

FIGURE 4 Foreign Bodies Removed at Third Operation

edematous and moderately inflamed. Strands of fibrin are present in the interstitial fluid of the submucosa. Diagnosis: mild subacute and acute hemorrhagic gastritis.

As previously, the stomach contents were extremely tangled. Removal of this mass of sharp metal and glass was hazardous to the hand within the stomach. Much care had to be taken not to tear the stomach wall while removing pins and needles.

Examination of the material recovered at the third gastrotomy, nearly 6 years subsequent to the first, showed over 425 foreign bodies, including wire, pins, toothpaste tubes, glass, tacks and so forth (Fig 4). A nail file was recovered in 3 pieces. The total weight was 295 gm. The convalescence was uneventful.

In the three gastrotomies, 1329 foreign bodies, with a total weight of 943 gm., were successfully removed.

At present the patient is not ingesting foreign bodies so far as is known. He is quite stable mentally and has just been released on parole. He states that he feels in perfect health and denies eating other than a normal diet.

SUMMARY

A case is reported in which, at three operations

over a period of six years, more than 1300 foreign bodies, weighing nearly 950 gm., were removed from the stomach.

DISCUSSION

DR ARTHUR W ALLEN, Boston DR Wheeler's case made exactly the same impression on me that it obviously has made on you. I have had no such experience as this in dealing with foreign bodies in the stomach. I do not mean to imply that in Massachusetts there is a lower percentage of mentally unstable persons than in Vermont, but for some reason or other I have not encountered any one with such an extreme craving for a metallic diet.

There are certain interesting features of this case that I should like to mention. One is that this is the highest gastric acidity I have ever seen recorded. One wonders whether the high acidity had any bearing on the patient's desire for such a diet, or whether the presence of the foreign bodies had an influence on the activity of the acid cells.

A striking fact concerning traumatic ulcer is brought out. Dr Wheeler very properly excised the enormous ulceration in the first operation, since it was perforating, but in the second and third, he left the benign ulcers alone. In spite of the very high gastric acidity, this patient apparently had no further trouble from peptic ulcer after the foreign bodies were removed. This is at least some evidence that there are other factors in the development of peptic ulcer than trauma and acidity, although acidity is necessary in the production of any experimental ulcer.

In addition to the psychopathic patient who swallows foreign bodies, there are certain normal people who accidentally get into similar difficulties. One of the most interesting cases of this sort that has come under my care was that of a middle-aged woman who was admitted to the hospital having had periodic attacks of complete pyloric obstruction. The x-ray examinations were slightly confusing in that there seemed to be a shadow, or possibly two shadows, in the stomach that resembled a polyp. These shadows shifted from one portion of the stomach to another. Dr Edward Benedict examined the patient gastroscopecally and saw two foreign bodies that looked to him like the pits of peaches or prunes. I performed a gastrotomy and removed two good-sized peach pits, one of which was quite smooth. The symptoms were doubtless due to the occasional engagement of one of these foreign bodies in the pyloric ring. The patient had no recollection of having swallowed these stones.

I believe that one of the earliest gastrotomies for foreign body at the Massachusetts General Hospital was done by Dr Maurice Richardson, when he operated on a man who had inadvertently swallowed his false teeth.

STRUMA LYMPHOMATOSA

Report of a Case Complicated by Myxedema

NICHOLAS S. SCARCELLO, M.D.,* AND RAYMOND H. GOODALE, M.D.†

WORCESTER, MASSACHUSETTS

STRUMA LYMPHOMATOSA (Hashimoto's disease) is a lymphoid goiter characterized by a growth of lymphatic elements and the formation of lymphoid follicles, together with certain changes both in the parenchyma and interstitial tissues of the thyroid gland. The condition was first described by Hashimoto¹ in 1912.

Hashimoto considered this disease a separate entity, not to be confused with Riedel's² disease. The essential clinical feature of the latter is a widespread involvement of the extrathyroid tissues in a diffuse sclerosis that appears to originate in part of the thyroid gland.

Very little was reported on this subject until Ewing³ in 1922 confused the picture by coming to the conclusion, following the study of 4 cases, that Hashimoto had described the earlier and Riedel the later stages of the same disease, which he called a benign granuloma of the thyroid gland. As a result of Ewing's view, no attempt was made in the numerous subsequent reports to distinguish between these two conditions. Even within the last few years several authors have held to this view. The assertion of Renton et al.⁴ in 1938 that Riedel's disease is characterized by lymphocytic infiltration with or without giant cells conforms closely to Hashimoto's description and not to Riedel's. Jaffe⁵ whose work, published in 1937, was chiefly confined to autopsy material, also supported Ewing by urging that the differences between the two conditions are qualitative only.

Boyden, Collier and Bugher,⁶ in 1935, stated: "It is our opinion that the conditions described by Riedel and Hashimoto cannot be differentiated either clinically or pathologically. Furthermore, we do not believe that the process is a distinct entity." Vaux,⁷ in 1938, came to the conclusion that Riedel's disease and Hashimoto's disease are stages of the same pathologic condition. Microscopically three stages, which merge into each other, can be distinguished — early, intermediate and late. The pathologic changes are the same in all stages, the degree of change being the varying factor. Eisen⁸ in reporting 7 cases of Riedel's struma, 3 of which were of the Hashimoto type, concluded that the two conditions are different morphologic manifestations of the same disease process.

On the other hand, numerous authors have expressed the opinion that the diseases are distinct entities. Graham and McCullagh⁹ in 1931 and Graham¹⁰ in 1931 from a review of the literature pointed out that Riedel's disease and struma lymphomatosa are distinct and distinguishable. Graham stated that of the 104 cases reported in the literature, 41 could be accepted as Riedel's disease and 24 as Hashimoto's disease, the remainder coming under the different forms of chronic thyroiditis. As a result of his work, the cases subsequently reported were more clearly differentiated as Hashimoto's or Riedel's disease, although enough confusion still exists to make it difficult to classify some of the cases.

Hashimoto's views were upheld and in part confirmed by Heineke¹¹ in 1914 and Reist¹² in 1922. Williamson and Pearse¹³ in 1925, and again in 1929, described the same condition under the name of lymphadenoid goiter. Hellwig¹⁴ in 1938, Clute, Eckerson and Warren¹⁵ in 1935, Mallory¹⁶ in 1935 and 1936, Emerson¹⁷ in 1935, Gilchrist¹⁸ in 1935, McClintock and Wright¹⁹ in 1937, Lee and McGrath²⁰ in 1937, Lee²¹ in 1935, Poer, Davison and Bishop²² in 1936 are also in essential agreement.

However, the apparent confusion still exists. When Perman and Wahlgren²³ in 1927 tried to prove their view in reporting a case of true Riedel's disease, they were able to show that specimens of pathologic tissue removed at two operations a year apart were of almost identical histologic structure, thus refuting the view that in the early stages of Riedel's disease the histologic findings correspond to what Hashimoto described.

Opposed was a parallel case published by Heyd²⁴ in 1929, in which the material removed at the first operation was typical of Hashimoto's disease, whereas a section removed thirteen months later showed an increased fibrosis, suggesting an approach to Riedel's disease.

It is obvious that more work and experience with cases of these diseases are needed to clarify the existing opinions.

Joll,²⁵ who has published the most recent work on the two conditions, whose thorough survey of the literature is excellent and whose personal *experience is greater than that of any other person*, — he has had 51 cases in his private prac-

*Assistant urologist, Worcester City Hospital, and instructor in urology, University of Vermont College of Medicine.

†Pathologist, Worcester City Hospital, and associate professor of experimental pathology, Boston University School of Medicine.

tice and the communicated knowledge of 30 unpublished ones,—is thoroughly in accord with the belief that the diseases are two different entities. His views should be given preference until other investigators have collected as great a number of cases or can in other ways disprove his findings.

Hashimoto claimed that the disease rarely occurred before the age of forty; this age incidence was confirmed by Joll, although the latter knew of a case in a girl of ten. A few cases between the ages of twenty and forty are recorded in the literature. In Riedel's disease, the highest incidence occurs earlier in life, that is, between the ages of twenty-five and thirty-five. In the cases so far reported, there is a marked preponderance of women among patients with Hashimoto's disease, whereas almost the reverse is true in Riedel's disease.

Joll has thoroughly reviewed the pathologic anatomy and histological studies, so that they do not require repetition. Although numerous views have been expressed, the etiology of these diseases remains unknown.

Several recent authors differ as to whether these cases can be diagnosed clinically. Joll believes that once the problem has resolved itself into a differential diagnosis of Hashimoto's and Riedel's diseases, a diagnosis can be made. He states:

A firm goitre which appears in a middle aged patient, usually a woman, reaches its maximum in a few months, and involves every part of the gland, causes only a moderate degree of dyspnoea, but produces neither serious pressure effects, thyrotoxic symptoms, pain, tenderness, pyrexia nor other inflammatory phenomena, is almost certainly a struma lymphomatosa. If to these features be added *absence* of any evidence of involvement of extrathyroid tissues and *presence* of some degree of hypothyroidism, the diagnosis is placed beyond a peradventure

Boyden et al.⁸ state, "Positive clinical diagnosis of the condition is practically impossible either before or at the time of the operation, and one must depend on the pathologist to rule out malignancy, especially when clinical findings suggest Riedel's disease." Clute et al.¹⁰ remark, "It is believed that rarely, if ever, can a diagnosis of struma lymphomatosa be made from clinical examination." Graham,^{9,10} on the other hand, believes that a clinical diagnosis should be made on clinical and gross findings, but that a preoperative diagnosis in cases of hyperthyroidism is impossible.

The following listing of characteristic findings is taken from Joll²⁵:

HASHIMOTO'S STRUMA

It preponderates in women from forty five to sixty years of age.

There is a tendency to myxedema.

All parts of the thyroid gland are involved, but nothing outside. The goiter is sometimes large but never woody hard

Pressure effects are seldom severe.

The histologic structure, which varies with the stage of the disease, is characteristic.

RIEDEL'S DISEASE

It occurs in younger men and women than does struma lymphomatosa.

There is little tendency to myxedema except after radical operation

The disease is usually unilateral with extension to extrathyroid structures. The goiter is small, intensely hard and smooth

Grave pressure effects are the rule

The mass is formed of dense scar tissue

Nearly all authors agree that surgical intervention in cases of struma lymphomatosa is contraindicated, especially in those associated with any signs of hypothyroidism. It is justified only in cases associated with hyperthyroidism; even then, they hold, only enough of the gland should be removed to relieve pressure symptoms or to establish a diagnosis, thus ruling out cancer. All are agreed that myxedema develops in over 50 to 60 per cent of cases, and that following operation this is in most cases brought on much earlier. If struma lymphomatosa is diagnosed and not treated, the basal metabolism rate should be determined frequently to detect the onset of myxedema. Whenever signs of hypothyroidism are evident, thyroid medication should be instituted.

Renton et al.⁴ have had good results in the treatment of struma lymphomatosa with x ray and recently with radium therapy. They think that the latter is almost a specific for this type of goiter, and 1 case that they have followed for five years has shown no signs of hypothyroidism.

The following case is interesting in that it occurred in a young woman who was followed clinically for thirteen years.

CASE REPORT

A 26-year-old woman was first seen at a Boston clinic in January, 1926, when she complained of a goiter. She had had this for 3 years and 6 months and had noticed increasing nervousness and a weight loss of 25 pounds. The basal metabolic rate on entry was +41 per cent, the body weight 150 pounds. A subtotal thyroidectomy was performed on January 22, and the specimen was reported to show primary hyperplasia, follicular type. The clinic record states that the patient was markedly improved after operation; by October, 1926, the basal metabolic rate was -4 per cent and the body weight 190 pounds. When she returned to the clinic in April, 1938, she weighed 245 pounds. The blood pressure on two occa-

sions was 134/100 and 158/130, but later fell to 120/70. The basal metabolic rate was -23 per cent.

The patient was placed for 8 days in a Boston hospital, where, after being put on an 800-calorie diet and given diuretics and small doses of amphetamine (Benzedrine), she lost 23 pounds. She felt much improved. She returned to the hospital in May, where she remained for 3 months. The weight was then 236 pounds and the basal metabolic rate -24 per cent. A systolic murmur was noted over the mitral area. A chest examination by fluoroscopy and stereoscopy showed the heart to be enlarged, so that there was a suggestion of rheumatic heart disease with mitral stenosis. The urine continually showed a slight to large amount of albumin. The patient was again placed on an 800-calorie diet and given Salyrgan and small doses of thyroid. About 10 days after admission jaundice was noted and there was marked tenderness under the costal margin. Duodenal drainage showed much pus and bile pigment. The blood bilirubin rose progressively from 1.6 to 19.0 mg. per 100 cc. With dehydration the nonprotein nitrogen rose to 50 mg. per 100 cc. and the patient was drowsy and irritable. When fluids were given she was more edematous, and ordinary diuretics did not cause diuresis. Injections of 50 per cent glucose intravenously, however, did produce a good diuretic effect. A gallop rhythm was noted during this period. X-ray examinations of the skull and of the long bones were negative. An electrocardiogram showed normal rhythm with low voltage and an inverted T_4 . By the middle of August, the jaundice had entirely disappeared and there was less abdominal tenderness, but the patient was still quite weak, and cyanotic on the slightest exertion. She continued to be markedly edematous in spite of the use of vitamins, ammonium chloride, potassium chloride, 50 per cent glucose and digitalis. No definite diagnosis was made. The patient was discharged on August 20.

Following discharge the patient remained at home and in bed. One of us (N. S. S.) was called on August 24, when she showed marked edema of the abdomen and lower extremities. The abdomen was redundant and reached the level of the junction of the upper and middle thirds of the thighs. She had become almost anuric, having passed but 120 cc. of urine in 48 hours. Other physical findings were the same as those in the previous hospital entry. The fluids, which had been restricted, were forced, and the patient was treated symptomatically. She began to show marked improvement after the 5th week at home. By November the pitting edema of the extremities had decreased to a point where it was barely noticeable. Edema of the abdomen had markedly receded, so that it barely overlay the inguinal fold. The patient continued, however, to have localized areas of tenderness, chiefly over the abdomen and lower extremities, varying from day to day. By December she was voiding 900 to 1200 cc. of urine, although her intake was limited to 900 cc. Several attacks of jaundice in this interval were transient and cleared up in 4 or 5 days. At about this time the nails became very brittle and the loss of hair of the head became very noticeable. However, the beard increased so that it required shaving.

In the first week in December the patient became mentally upset and disturbed and was very irrational, incoherent and noisy. At this time she was seen by a neuropsychiatrist, who considered the case to be one of beginning beriberi with peripheral neuritis. She had improved considerably by the early part of January, 1939, so that she could help herself in bed; but she began to put on weight again, the abdomen began to enlarge, and the extremities showed a return of pitting edema. On February 13, she was referred to the Joseph H. Pratt Diagnostic

Hospital, under the supervision of Dr. S. J. Thannhauser.

Physical examination showed an extraordinarily large young woman lying helpless in bed. The facies suggested myxedema (Fig. 1). She looked pale. The blood pressure was 100/75 (right arm). The skin was markedly roughened, especially over the lower forearms and the backs of the hands, where there was superficial scaling over a reddish mottling. The skin appeared atrophic in these areas. The superficial scaling was seen also over

FIGURE 1.

Note the obesity and the few hairs; the patient shaved every few days.

the lower legs (Fig. 2). There was an obvious beard around the chin and some hair near the breasts. The pubic hair had a male distribution. The pupillary reactions were normal. The scleras appeared clear; the palpebral conjunctivas were pale. The external ocular movements were normal with no lid lag or nystagmus. The fundi showed well-defined disks, and the retinal fields were normal. By confrontation test the visual fields were adequately large and not defective. The teeth were widely spaced. The tongue was well papillated. The size of the heart could not be determined by percussion because of the obesity; the action was rhythmical and rather rapid. A late systolic blowing murmur was heard along the left sternal border and especially well in the pulmonic area. The vascular pulsations in the neck were wide. No other murmurs were heard in the heart. The lungs were normally resonant, and no rales were heard; the breath sounds were of normal character. The abdomen was flabby, broad and table-like in complete relaxation. No liver or spleen could be felt. There were many striae in the lower quadrants of the abdomen, some appearing reddish and others as pale white cicatrices. There was moderate pitting edema of the dependent abdominal wall, which overlay the flanks and pubis. In the fold of this apron there were excoriations, more marked on the left

side. The arms were small compared with the elephantine legs. The fingernails were almost completely white, owing to superimposed transverse white lines.

Laboratory studies gave no helpful data for the diagnosis of the underlying condition. Basal metabolic studies were not satisfactory.

The patient was kept on a 1000-cc. intake; the urinary output varied between 300 and 550 cc. Early in her stay

FIGURE 2.

The legs show edema and superficial scaling.

the drainage of the edema fluid from the legs and thighs was carried out by the use of cannula-like needles, but this was not continued because of the appearance of inflammation in the areas of drainage and a rise in the white-cell count, even in the absence of fever.

A skin biopsy was reported as consistent with scleroderma. Following this there was infection of the biopsy wound and a purulent infection of the tip of the left middle finger, and the patient had fever for the first time. Sulfanilamide—15 gr. every 4 hours—was therefore started, but its effect could not be followed since the patient was discharged home on the following day. The fever eventually disappeared.

Following discharge the patient became progressively worse, and died about 3 weeks later, or 13 years after she had come under observation.

Autopsy. The body was that of an obese, edematous woman, 155 cm. tall and weighing 180 pounds. The breasts were practically nonexistent because of the lack of breast tissue. There was extreme pitting edema of the ankles, legs and thighs. The face showed a moderate beard on both cheeks and the chin, with a slight tendency to growth of hair on the upper lip. The pubic hair was scanty and triangular in distribution; the axillary hair was normal. Both legs and arms showed considerably more than the usual amount of hair for a woman. There was a well-healed surgical scar, 8 cm. long, extending around the base of the neck. There were large intertriginous erosions in both inguinal regions, due to the sagging of the abdominal wall onto the thighs. There was a 6-by-1-cm. draining sinus in the lateral aspect of the thigh just below the crest of the ilium. The skin of the

face showed an extremely fine wrinkling; that of the abdomen and legs was coarser, and was peculiar in that the epidermis seemed to be separated from and wrinkled over the dermis.

Dissection of the thyroid area revealed two small pieces of what was probably the thyroid gland, totaling less than 1 cm. in diameter.

The heart weighed 450 gm. The myocardium was pale and flabby. The coronary arteries and valves were normal.

The liver weighed 2100 gm. It cut with increased resistance, and the cut surface was somewhat yellow. Close examination suggested an exceedingly fine distribution of excess fibrous tissue throughout the liver, but there was no gross scarring. The lobular markings were normal.

The pituitary gland, adrenal glands and ovaries showed no tumors grossly or microscopically.

Microscopically, the peritracheal tissue consists of a dense collagenous scar, with some muscle embedded in it; scattered through the scar are slight remnants of thyroid tissue made up of flat epithelium or Hürthle's cells making a feeble attempt at acinar formation; not more than 15 acini that contain colloid are found. The thyroid tissue is chiefly represented by disorganized masses of Hürthle's cells with lymphocytic infiltration about them

FIGURE 3.

This remnant of the thyroid gland shows a poorly formed acinus and lymphocytic infiltration.

(Fig. 3).^{*} Also embedded in the scar tissue is a normal-appearing parathyroid gland. The heart presents a striking picture throughout most of the section—especially in regions where muscle bundles are transected—of isolation of each muscle bundle by delicate fibrous tissue and edema. About the blood vessels the amount of fibrosis becomes more marked, and in many places the muscle lobules are separated by fatty infiltration. In some areas many fibroblasts, some appearing quite young, are visible.

^{*}These findings are practically identical with those in the thyroid tissue removed in 1926.

Occasional polymorphonuclear cells and lymphocytes are scattered through this delicate, extensive fibrous stroma. Many dilated capillaries, where endothelial walls appear slightly thickened, are present, and many spaces that appear to be widely dilated lymphatics are also in evidence. The liver shows extreme fatty metamorphosis, so that the tissue looks like pure fat except for small patches of liver cells near the portal areas that are relatively normal. The most striking feature is the uniformity of the size of the cytoplasmic vacuoles. Sections of skin are consistent with scleroderma.

A culture of the edema fluid from the left thigh near the incision showed a hemolytic streptococcus.

SUMMARY

A case of struma lymphomatosa (Hashimoto's disease) is reported. The case is of particular interest because the patient was only twenty-six years old when first seen, because the initial symptoms were those of hyperthyroidism, because she developed myxedema during the thirteen years that the case was observed, and because thyroid tissue removed in 1926 could be compared with that obtained at autopsy in 1939.

LIMITATIONS OF GASTROSCOPY*

I. R. JANKELSON, M.D.,† AND CHARLES W. McCCLURE, M.D.‡

BOSTON

ALTHOUGH fully cognizant of the valuable objective information that can be obtained through the semiflexible gastroscop in intragastric disease, we have nevertheless found that this method of examination, like every other endoscopic one, has distinct limitations. Since these are not sufficiently emphasized in the current literature on gastroscopy, and are therefore probably not well recognized by the medical profession, we believe that to call attention to them is timely and may help in the proper evaluation of the clinical use of the gastroscop.

In 1932 the Wolf-Schindler gastroscop was devised and its practicality demonstrated. Previously, when only rigid gastroscopes were available, there had been a distinct danger of perforation of the esophagus during gastroscopic examination. Moreover, it required considerable skill to introduce the gastroscop with even relative safety and com-

fort to the patient. The procedure was therefore limited to a small group of experts. All this was changed completely when the semiflexible gastroscop became available. To introduce it requires no unusual skill, and with some experience the examination can be performed expeditiously, safely and without undue discomfort.

In all large medical centers, as well as in many small hospitals, examination through the semiflexible gastroscop is now performed and dependable observations are made. This has resulted in a large and rapidly growing literature on the subject. Three monographs on gastroscopy have been published since 1932: Moutier's¹ in French and Henning's² in German were published in 1935, and Schindler's³ book in English appeared in 1937. Much of this literature is pioneer work; besides contributions to the early descriptions of the technic and of the indications and contraindications of gastroscopy, numerous papers⁴⁻⁷ have outlined the normal gastroscopic picture and its changes in the presence of disease. The gastroscopic findings

*From the Gastrointestinal Clinic, Boston City Hospital.

‡Assistant professor of medicine, Boston University School of Medicine, and junior visiting physician, Boston City Hospital.

in such common diseases as gastritis,⁸⁻⁹ gastric ulcer¹⁰⁻¹¹ and cancer¹²⁻¹⁵ have also been described; the differential diagnosis of ulcer and cancer of the stomach as seen through the gastroscope has been discussed and the roentgenographic and gastroscopic evidences of intragastric disease compared.¹⁶⁻¹⁷

A perusal of the literature reveals a great deal of enthusiasm among the authors, who record many cases, often checked by roentgen-ray study, surgery or autopsy, wherein this method of examination disclosed otherwise hidden or overlooked disease of the stomach. In a previous contribution we¹⁸ have reported a series of similar cases. However, in that study we called attention to some difficulties in diagnosis and recorded some errors in interpretation. With growing experience in gastroscopy, we became more conscious of the many difficulties of the method, the shortcomings of the instrument and the various limitations of the procedure.

During the last three and a half years we have performed over 800 gastroscopies, every case having been examined and the observations checked by both of us. All cases had at least one gastrointestinal roentgen-ray examination. In all cases the gastroscopic findings were compared with the roentgen ray films, as the only other method of morphological visualization of the stomach short of an exploratory laparotomy. This has taught us the value of both procedures; and as clinicians who use every method at our disposal to arrive at a correct diagnosis, we are convinced that neither method should supersede the other. On the contrary, they complement one another, and both should be used in cases where intragastric disease exists or is suspected. The range of the gastroscope is extremely limited as compared with that of the roentgen ray. It can show the appearance of the mucous membrane of the stomach, but it is, of course, completely unsatisfactory in lesions that involve any other portion of the digestive tract. Another limitation is the inability to obtain biopsy specimens; microscopic confirmation of the observed lesion or lesions is thus rendered impossible. Furthermore, even in its limited field the gastroscope is not infallible. Because of constantly changing view caused by both gastric peristalsis and respiratory movements, small localized lesions of the gastric mucosa may be visualized only at variable times during a gastroscopic examination, and may thus be entirely overlooked. Often one of us has readily located a small lesion such as a superficial ulcer or small polyp, whereas the other at the same examination has found it most difficult to confirm the observation. Also, the discovery of changes in the mucous mem-

brane of the stomach does not necessarily mean that the symptoms are caused by such changes. In fact, secondary changes in the gastric mucosa often accompany disease of the duodenum, gall bladder, liver, heart or other organs. Furthermore, the symptoms of hypertrophic gastritis, especially when it is accompanied by fissures or superficial ulcerations, may simulate those of peptic ulcer. However, if a duodenal ulcer is demonstrated roentgenologically and evidence of hypertrophic gastritis is shown by gastroscopy, we believe that the former condition in all likelihood explains the symptoms. On the other hand, the same gastroscopic findings in the absence of a demonstrable ulcer either in the stomach or duodenum probably account for the digestive symptoms. Thus their relation to all the other evidence determines the diagnostic significance of the gastroscopic findings. In other words, only by intelligent coordination of all these data in the light of clinical experience and judgment can the errors of diagnosis be minimized.

Lesions of the antrum involving the lesser curvature may not be demonstrated by gastroscopy. The fault is with the gastroscope in use at present, which does not permit the proper visualization of this portion in a certain type of stomach. Unfortunately, this is a very frequent seat of peptic ulcer and early carcinoma, which may thus be overlooked in a gastroscopic examination. The following case is illustrative.

CASE 1 E H., a 59 year old man, had epigastric pain of 2 years' duration. The pain usually developed 2 hours after meals and was relieved by the intake of food or soda. Coincidentally there were gas and frequent eructations. The bowel movements were regular, and there had never been bloody or tarry stools. Physical examination was essentially negative. Roentgen ray examination showed in the prepyloric region a constant, irregular, filling defect suspicious of early carcinoma. Gastroscopy revealed evidence of atrophic changes in the mucosa but no demonstrable lesion in the antrum. Because of the suspicious roentgenological findings, the patient was operated on, and an ulcerating lesion on the lesser curvature of the antrum was found and resected, microscopic examination showed it to be benign.

Gastroscopy may fail to demonstrate cancer in cases in which the stomach cannot be properly distended with air, and considerable food residue, which has not been evacuated by the usual procedure, may obstruct the view. At times the differential diagnosis between cancer of the stomach and localized hypertrophic gastritis is extremely difficult or even impossible on a single examination with a gastroscope. Case 2 is cited to demonstrate the latter difficulty.

CASE 2 I O., a 62 year old man, was admitted to the hospital complaining of abdominal pain and alternating constipation and diarrhea of 4 or 5 months' duration. Dur-

ing this period he had lost 6 pounds in weight, had become weak and had lost his appetite. Physical examination was entirely negative. The chemical constituents and the cells of the blood were within normal limits. The stools contained no occult blood. Roentgen-ray examination raised the question of a scirrhus carcinoma of the stomach. Gastroscope revealed a mucous membrane that appeared infiltrated and showed large reddened and partially ulcerated ridges. The gastrosopic diagnosis was cancer of the stomach. The patient refused operation and is now, 16 months later, entirely symptom-free; he has gained weight and is able to follow his usual occupation.

Everyone realizes the difficulties of the clinician and the surgeon in differentiating some cases of ulcer of the stomach and ulcerating carcinoma. It was hoped—and as a matter of fact it has been stated in the literature—that this differential diagnosis could always be made by gastroscope. However, this is not always so in our experience. We have erred in both directions in such cases and do not depend on a single gastrosopic examination; but if the case can be followed by repeated examinations, the diagnosis often becomes obvious. Case 3 illustrates the difficulties that can be encountered.

CASE 3. P.S., a 46-year-old man, was admitted to the hospital complaining of heartburn and belching of 20 years' duration. Two years previously the patient had an episode of melena and syncope. Roentgen-ray examination of the gastrointestinal tract at that time revealed nothing abnormal. One month prior to entry the patient developed epigastric pain associated with belching. He had lost 8 pounds. Physical examination on admission revealed an apprehensive patient with tenderness just below the umbilicus. Gastric analysis revealed no free hydrochloric acid, even after the administration of histamine. A gastrointestinal roentgen-ray examination showed an irregular mass occupying the superior and medial borders of the cardiac end of the stomach. Gastroscope showed a large, irregular, ulcerating lesion just below the cardioesophageal opening, which was interpreted as being a cancer. At operation a large soft peptic ulcer was found on the anterior wall of the cardia. It was resected and was shown microscopically to be benign.

One of the most trying experiences in performing a gastroscope is to examine a patient in whom the roentgen-ray examination has demonstrated a definite niche about the upper third of the lesser curvature of the stomach, and still to fail to visualize the lesion; we have had several such experiences. The following case, in which two gastroscopies failed to show the ulcer, is illustrated.

CASE 4. M.A., a 67-year-old man, entered the hospital complaining of epigastric distress that came 1 to 2 hours after meals and was relieved by the ingestion of soda. He had lost 15 pounds in weight and was referred to the hospital because he did not respond to ambulatory ulcer management. Physical examination was essentially negative. Laboratory examination revealed no relevant deviations from normal. X-ray examination showed a large ulcer

niche on the lesser curvature. Two gastroscopic examinations showed a diffuse reddening of the entire gastric mucosa and no evidence of an ulcer.

In stomachs examined postoperatively the gastroscope frequently gives decisive information of the presence or absence of gastritis, marginal ulcer and so forth. However, it is an unpleasant experience to have to record the inability to visualize a stoma when roentgen-ray study has demonstrated a well-functioning gastroenterostomy. A marginal ulcer, particularly if it is on the jejunal side of the stoma, may also be overlooked. This is illustrated by the following case.

CASE 5. A.D., a 39-year-old man, had five admissions to the hospital between June, 1934, and July, 1939. A diagnosis of duodenal ulcer was made in 1934, and because of persistent pyloric obstruction a posterior gastroenterostomy was performed. On July 21, 1938, a roentgenological diagnosis of a functioning posterior gastroenterostomy was made. An old duodenal ulcer was also shown, and the question of a marginal ulcer was raised. A gastroscope performed on July 25 showed greatly enlarged and tortuous rugae. No gastroenterostomy stoma was seen. Eleven months later the patient was readmitted complaining of severe epigastric pain of 3 hours' duration. The abdomen was rigid throughout. There was marked muscle spasm and rebound tenderness. The patient was operated on the same day, and a perforation of a marginal ulcer was found.

In the presence of an hourglass constriction of the stomach the distal portion cannot be visualized. Thus, although the actual constriction can be seen, the underlying disease may often be overlooked.

Besides these limitations certain other conditions prevent a gastroscope or contraindicate the introduction of the instrument. In our experience, a small percentage of patients are temperamentally unfit to go through with this examination. In such cases, because of the danger to the uncooperative patient as well as possible damage to the gastroscope, the examination cannot be properly performed. Any serious disease, obstructive or otherwise, of the esophagus is a contraindication to gastroscope. In cases of severe curvature of the spine or arthritis of the cervical spine, it is frequently impossible. Serious cardiac disease and aneurysm of the aortic arch contraindicate the procedure, as does uncontrollable cough or dyspnea, whatever the cause. Gastroscope is best avoided in peritonitis, perforated ulcers and acute illnesses with fever. We have also refrained from performing it during acute gastric hemorrhage, although others do not consider this a contraindication. In most of these cases morphologic evidence of intragastric disease can be obtained by roentgen-ray examination.

SUMMARY

One can say that the intelligent co-ordination of roentgen-ray and gastroscopic examinations as the only two clinical methods for the visualization of the stomach will diminish the error in gastric diagnosis. The two procedures are not antagonistic; on the contrary, they are complementary. Whereas roentgenograms give a great deal of morphological information about the stomach and other intra-abdominal organs, the gastroscope is limited in its field of usefulness. Even failure to observe any pathologic lesions or changes within the gastric mucosa does not exclude intragastric disease. On the other hand, when changes are seen through the gastroscope a lesion is undoubtedly present, but the interpretation of the findings may be difficult. The differentiation between a gastric ulcer and an ulcerating carcinoma is not always possible, and in such cases, re-examination after an interval of several days to several weeks may be necessary for a proper diagnosis. Obviously, its accuracy depends to a large extent on the experience of the observer and his ability to co-ordinate the available gastroscopic, roentgen-ray and clinical evidence. Finally, certain conditions outside the stomach may justify a gastroscopy or may make

it inadvisable or even dangerous. In such cases, for the safety of the patient, gastroscopy should be avoided.

MEDICAL PROGRESS

RADIATION THERAPY IN GYNECOLOGY

JOE V. MEIGS, M.D.*

BOSTON

RADIUM and x-ray treatment are used so extensively in gynecology that a review of their uses and purposes seems called for. Radium and the short-wave lengths of the x-ray both act on tissue in much the same way. They are never stimulating but always destructive. They act to inhibit activity of glandular structures, to inhibit mitoses in malignant growths and ultimately to cause fibrosis of tissue and arteriosclerosis. There has been much written about stimulating doses, but it is likely that radiation releases inhibiting influences and that normal function follows. Its effect on moist skin is to cause a cessation of the activity of sebaceous and sweat glands. That on ovarian function is to cause cessation of the activity of persistent and vulnerable follicles, and if the treatment is not too heavy, to allow normal follicles to recommence to function. That on inflamma-

tory tissue is to cause death of lymphocytes and a rapid softening and death of tissue cells. It is improbable that there is a direct inhibiting or killing effect on bacteria. In other words, radium and x-rays are destructive agents, and this action is used in treating gynecologic lesions.

Radium is used in two forms—the active radium salt and radon, the emanation; both, so far as gynecology is concerned, exert the same effect. Radium is the more stable, expensive and unwieldy of the two. Radon is so unstable that losses in potency must be accounted for hourly or daily; however, it is less expensive than the active salt and can be put up in many different forms, strengths and sizes. Both are employed in various types and shapes of applicators with varied densities in their walls, either to allow the use of caustic beta rays or to screen them out and permit the use of only the very short, penetrating waves of gamma radiation. So far as gynecology

*Instructor in surgery, Harvard Medical School, visiting surgeon, Massachusetts General Hospital, and surgeon, Pondville Hospital.

is concerned, nearly all treatment is given in heavily screened applicators, in order to keep out the caustic beta rays whenever possible. Seeds, generally of 1 to 5 millicuries strength, are used for infiltrating nodules of tumor too small to permit the use of platinum needles. In most large areas, however, platinum needles are more and more taking the place of seeds; they vary in strength from 5 to 25 mg., and are of varying lengths and thicknesses. Radiation in cavities such as the cervical canal in cases of cancer is given by means of radium or radon in hollow tubes of brass, silver, gold or platinum. These applicators may contain tubes of any strength from 25 to 500 mg. or millicuries.

X-ray treatment is now in the throes of practical experimentation with higher voltages. The old 100-kv. machine is used only for superficial treatment. Even the 200-kv. machine, which was considered a high-voltage machine a few years ago, is now thought of as having too low a voltage. The 400-kv. or 500-kv. machine is considered to be adequate by some, but the 1000-kv. one¹ is now most talked of, and great results are expected from it. Enough time has not yet passed to allow proper evaluation of these higher voltages, and it remains to be seen whether the results with the 1000-kv. machine will surpass those obtained by the 200-kv. one. Human tissue can stand just so much radiation without undergoing necrosis, and if the amount of radiation needed to cause necrosis can be delivered into the depths without too great damage to the skin by the 200-kv. machine, the 1000-kv. apparatus may do no better, except that the skin will not be injured so much. Bladder symptoms,² bowel hemorrhages, intestinal obstruction, ureteral block and extensive pelvic fibrosis must be guarded against, and if any one of the machines mentioned can prevent such calamities and yet give a lethal dose to a deep, malignant growth, it should be the one of choice. A machine is now being made which will deliver 3000 kv. Great care and extensive study must be carried out before such an agent is used on human beings, and even then its employment should be confined to experts, and not be applied in routine therapy for a long time.

There is no doubt that the experience of the last few years with x-ray treatment in addition to radium has been highly significant in the treatment of cervical lesions.³ After a long success with radium alone, the day of combined treatment has come. Its results are more satisfactory than the previous ones, and we may see a time when radium is entirely discarded. Radiation treatment is changing, and with more intelligent use of more

powerful machines and even with new types of rays greater improvement may be expected.

Vulva. Pruritus vulvae, if of the moist type and due to oversecretion of the sebaceous and sweat glands, is well treated by light doses of x-rays. The dry type seen in patients with early senile changes does not respond well to radiation; estrogenic hormones given by mouth, intramuscular injection, or in salve or suppository form are more effective, but vulvectomy may be necessary.

Leukoplakic vulvitis, a precancerous lesion, due to overgrowth of the top layers of the skin with a marked lymphocytic infiltration beneath, is not well treated by radiation. Estrogenic hormones can be used for a short time, and if a result is not obtained quickly, complete removal of the vulva should be carried out.

Kraurosis vulvae, probably the end result of leukoplakic vulvitis, a dry lesion, is not suitable for radiation. The thin, parchment-like skin with its thick underlying connective tissue, characteristically accompanied by itching, is best let alone unless the severity of the symptoms makes necessary some form of treatment, when complete vulvectomy is the operation of choice.

Most radiologists and gynecologists have learned that the heavy doses of radium or x-ray necessary to destroy vulval cancer cause extreme discomfort and pain, and have given them up. The only proper treatment is complete vulvectomy with bilateral radical dissection of both groins after the method of Basset. Taussig^{4, 5} has been America's greatest advocate of this operation, and his results surpass those of most other clinics. Vulval cancer is a disease of old women, but they are usually better surgical risks than they appear to be, and their life expectancy is longer with operation than it would be without; therefore radical surgery is justifiable. Some surgeons prefer to carry out a vulvectomy and to employ x-ray or interstitial radium treatment for the lymph nodes in the groins. This treatment is condemned, for the results are far less satisfactory than those following radical resection.

In certain cases recurrence of vulval cancer must be treated with radiation, and here it is best to use infiltration with gold seeds or platinum needles.

Clitoris. Carcinoma of the clitoris should be included under cancer of the vulva, and radical surgery—total vulvectomy and bilateral dissection of both groins—is to be preferred to any type of radiation.

Urethra. If excision of cancer of the urethra is possible, surgery is preferable to radiation. Sometimes it is not possible, and radium treatment is

instituted with the placing of platinum needles of proper length in the tumor, parallel to the urethra. The bladder is kept on constant drainage, and a massive dose of radium is given.

Cervix. Endocervicitis, once treated by moderate doses of radium in the cervical canal, is no longer so managed. Cancer of the cervix, whether squamous or adenomatous in type, whether early or advanced, is best treated by radium plus radiation by x rays. Some gynecologists prefer radium alone, often applying x-ray treatment over the lower abdomen and back, possibly adding a vaginal cone.⁵ Most gynecologists, however, prefer a combination of x-ray and radium; some give the radium first, and others the x-rays.

There is very little difference in the end results of any large series of cases, so long as they are adequately treated. In a recent report compiled by the San Francisco Gynecologic Society⁷ on the basis of statistics from ten clinics in Europe and America, there was slight variation in the results except for one clinic, and there the method used was identical with that employed in one of the other clinics, the better results possibly being explained by the predominance of early cases. In nine of the clinics with quite different methods practically the same end results were obtained. There has been a fair increase in good results from the added roentgen-ray treatment. This is accounted for by the further injury done to cancer cells already partially destroyed by radium and by fibrosis of the pericervical tissue, and not to the destruction of metastatic lymph nodes. Enough surgery has been done following radiation to demonstrate that most cancerous lymph nodes in the pelvis are not destroyed by radiation.^{6, 8} Unquestionably lymphatics are narrowed, cellular tissue is fibrosed, and cancer cells are injured, but destruction of cancer by radiation outside the field of the concentrated radium and x-ray treatment is not possible. However, fibrosis and destruction of lymph channels may easily prevent further extension of local disease. The work of Lynch,⁹ showing cancer cells in the radiated cervix subsequently removed by a total hysterectomy, and that of Taussig,⁶ who found cancerous nodes while doing pelvic dissections following radiation, offer proof that radiation does not destroy cancer outside certain areas.

The complications following treatment by radium or by radium and x rays are not uncommon and may be disastrous. The vesicovaginal fistulas seen may be due to too-vigorous treatment or to advanced disease that has penetrated to the bladder floor. Cystoscopy before radiation will ordinarily indicate the latter, and sometimes if the disease is extensive small doses are best, for if

the cancer is incurable, the patient's condition should not be made worse by too-powerful treatment. Rectovaginal fistulas are less common and are due to the same cause. For some reason they frequently heal spontaneously, but vesicovaginal fistulas practically never do so.

The necessity for careful investigation of the urinary tract² is obvious when the ureter is involved. Block of the ureter may be due either to the disease, to the disease together with swelling caused by radiation or to fibrosis following radiation. Every patient should be followed carefully by a urologist and given proper treatment, such as dilatation of the ureter or nephrostomy to prevent destruction of the kidney or ward off impending uremia.

Intestinal obstruction¹⁰ is not uncommon following x-ray treatment, and occurs most often because of the continued treatment over a piece of bowel that is fixed at some point in the pelvis. The obstruction may be in the large or small bowel. It may be a fibrous, nodular block or a long, narrow stricture. An x-ray ileitis is set up, and later fibrosis occurs. This complication may follow the use of radium, especially in the too-active treatment of cancer of the cervical stump. Here a piece of intestine may be adherent to the stump and the close proximity of the radium applicator may cause a burn and later an area of fibrosis. Obstruction is a serious complication, and the presence of intestinal cramps following radiation suggests injury to the bowel.

Swelling of the leg following radiation treatment of cervical cancer is not always due to recurrent disease in the broad ligament, and one must be sure that cancer is present before advising radiation in the form of x-ray treatment. Such swelling is often due to pelvic fibrosis and lymphatic and venous block.

In many cases, radiation in the treatment of cervical cancer fails completely because of radiation insensitivity. Greater salvage will occur when this failure to respond is recognized earlier. The effect of combined x-ray and radium treatment can be noted by biopsy of the tissue under treatment, and a fair estimate of the ultimate result can be made.¹¹ If the response is not good a poor result can be expected, and vice versa. If this poor response is recognized and if the tumor can be removed by operation, serious consideration should be given to radical hysterectomy and dissection of the pelvic lymph nodes.

In most groups of early cases of cancer of the cervix treated by x-ray and radium, the salvage is about 60 per cent, so that 40 per cent of early cases must end in death in spite of the fact that they receive proper treatment. It is probable, therefore,

that as more careful studies are carried out to determine what patients in the operable group are not responding to radiation and should therefore be submitted to a radical surgical procedure, a better than 60 per cent salvage will be effected. Surgery has its place in cervical cancer. It is a modest place, and operative cases must be carefully selected, but if radiation resistance is recognized early more cures will result by subjecting the proper patients to operation.

Taussig⁵ believes that x-rays will not kill the cancer cells in metastatic pelvic lymph nodes, and advocates dissection of the iliac, ureteral, hypogastric and obturator nodes in all early cases, especially those in which local vaginal disease can be destroyed with radiation. His end results from this operation are surprisingly good: of 11 patients with cancerous lymph nodes 3 are living and well without disease at the end of five years. The patients would surely have succumbed to the disease except for this ingenious operation. Surgery of the lymph nodes is better than radiation, and probably should be carried out.

Vagina. Cancer of the vagina, a very serious disease, should be treated like carcinoma of the cervix. External radiation through four portals should be given along with the intravaginal cone, in addition to radium needles in the center and the periphery of the tumor. The results will be poor. Fistulas, either in the bladder or rectum, will often occur. If the tumor lies in the outer vagina, dissection of the lymph nodes of the groin is essential if a good result is to be obtained. An operation of the Wertheim type can be undertaken in early cases, but it will never be so successful as radiation because of the great difficulty of removing the entire vagina. Even if it is removed, those tissues directly under the vaginal growth may be infiltrated by disease. Combined x-ray and radium treatment with the vaginal cone is the proper procedure.

Endometrium. Cancer of the endometrium is not primarily a lesion that should be treated by radiation. In some clinics radium is given to the exclusion of surgery, and the results as reported are fairly satisfactory. In most clinics the results by means of surgery are superior. Many gynecologists advise using intrauterine radium followed by x-ray treatment and then surgery, consisting of total hysterectomy—not of the radical type. Others advocate radiation in the uterine canal only, and then surgery. It has been very difficult to find an applicator that will destroy the cancer in the entire endometrial canal. Schmitz,¹² of Chicago, has devised such an apparatus. It is a Y-shaped piece of metal that contains needles

in the two arms of the Y and in the shaft; after being placed in the canal the arms can be opened so as to fit into the cornua of the uterus. This method is unsatisfactory because of the separation of the needles in the various parts of the applicator. The Pondville Hospital has been using one long gold needle that fits snugly into a Monel metal applicator 1-mm. thick, and extends from its base to its top. The uterine cavity is measured accurately before the needle is made. Applicators vary from 5 to 15 cm. in length, so that any uterine cavity can be radiated throughout by means of an applicator of proper length. With this the tumor of the endometrium can be destroyed along its entire length, but areas of tumor that penetrate into the wall of the myometrium are not affected. At Pondville the reason for using radium in the uterine cavity is to prevent extension of this disease by metastasis to the anterior or posterior vaginal walls. The presence of such nodules practically always means a fatal outcome, and little can be done except local infiltration with radon seeds. To prevent such extension the whole uterine cavity is radiated and six weeks later the patient is operated on, in the hope that the tumor will be nearly destroyed, that the lymphatics will be closed off and that any tumor cells that may be spilled in the vaginal vault at operation will be gravely injured. X-ray treatment of lymph nodes involved by this disease is not satisfactory, because they are in the aortic and renal regions and not in the pelvis. The surgery that is undertaken after x-ray treatment should include the removal of the entire cervix and both tubes and ovaries, because these areas are susceptible to metastatic involvement. Often after radiation a sterile peritonitis is found, with fibrin and adhesions all through the pelvis. The most important part of the treatment of endometrial cancer is its surgical removal. Radiation has its use in attempts to prevent metastases, especially those to the vagina, or implantation into the vaginal scar.

Fallopian Tube. Carcinoma of the fallopian tube is rare; the treatment is radical pelvic surgery.¹³ Radiation is only a secondary method of treatment, to be used after removal of the tubes, ovaries, uterus and cervix if an area of extension is found in the pelvis or if there are any evidences of pelvic metastases. The routine use of x-ray treatment is not essential.

Ovary. Cancer of the ovary is one of the most serious of all malignant lesions, and only about 9 per cent of patients with solid tumors survive for five years.¹⁴ The papillary cystadenoma of the malignant type gives about a 21 per cent five-year

curability. Surgery is the proper treatment,¹⁵ but if the tumor has become adherent, if there are areas that cannot be removed, or if there are metastatic nodules anywhere in the peritoneum, x-ray treatment should be resorted to. It should consist of rays directed against the metastases or extensions of tumor, the locations of which have been described to the roentgenologist as accurately as possible. Too many times the latter is called on to treat ovarian cancer without knowing where the radiation should be directed.

Certain types of endocrine tumors are extremely responsive to radiation, and if invasion has taken place anywhere in the peritoneal cavity, for instance, from a dysgerminoma of the ovary, this area should be treated immediately by x-ray, with some expectation of relief. Granulosa-cell tumors, supposedly radio-sensitive, may be radio-resistant, but x-ray treatment should be directed toward the metastases after they have been described to the roentgenologist.

There is no doubt that x-ray treatment prolongs life in inoperable cases of cancer of the ovary, but a cure is not effected. There are no authentic cases reported from the Massachusetts General Hospital of metastatic ovarian cancer that have been cured by x-ray treatment alone. It has made some of them operable, and following operation some of the patients have lived for a long time. By and large, x-ray treatment helps to prolong life and stop the accumulation of fluid. It is of extreme value for this reason, but radical surgery should never be avoided in the hope that x-ray treatment will furnish a proper substitute.

Benign Uterine Bleeding. In benign uterine bleeding in women near the menopause, radiation is extremely satisfactory. In any patient forty-five years of age or older who has abnormal bleeding proved by curettage to be benign, treatment by radium in the uterine cavity or by x-rays directed toward the ovaries is the one of choice. Every patient of this type who bleeds should be curetted to rule out cancer or submucous fibroids, and it is most satisfactory to place radium in the uterine cavity at that time. It is best given in the end of a long applicator that reaches the top of the fundus, so that there will be no scar in the cervix with subsequent pyometrium. Cases of bleeding after the menopause for which no reason can be found should never be treated by radium or x-ray, because of the possibility of obliterating the endometrial cavity, thus allowing the cause of the bleeding, such as a carcinoma or tumor of the ovary or tube, to be obscured. It is also possible to obliterate the cervical canal in such a way that the growth in the endometrial

cavity will continue to enlarge for some time before being discovered.

In young girls it is rarely necessary to use radiation for menorrhagia; usually hormones, such as progesterone and testosterone, will check such bleeding until the patient's own cycle has been re-established, which happens in most cases. Occasionally radium or x-ray in small doses can be used, but it is best not to treat this type of patient by radiation if it is possible to avoid it.

The effect of radium in benign bleeding cases is probably exerted on the ovary; it interferes with or destroys the follicles so that there are fewer or none left to secrete estrin. Not all the endometrium can be destroyed by a radium needle placed in the end of a long applicator in the uterine cavity, yet the bleeding does stop. Destruction of the activity of the ovary inactivates the endometrium; subsequently the latter atrophies, whereupon bleeding ceases. In about 95 per cent of cases with benign bleeding combined x-ray and radium treatment gives excellent results. There is no objection to x-ray treatment, but it is simpler, if a dilatation and curettage is to be done, to place radium at that time than to do the operation and then send the patient in for at least six x-ray treatments. It is purely a matter of convenience, not one of choice. Following radium treatment there is occasionally a moderate amount of vaginal discharge for two or three months. X-ray and radium are equally worth while, but radium is more convenient if it is available.

Fibroids. The treatment of fibroids with combined x-ray and radium should be confined to those patients who have a symmetrical, smooth tumor no larger than a grapefruit. Sending patients to the roentgenologist for treatment of fibroids by means of x-ray treatment without proper investigation of the uterine cavity and evaluation of the type of fibroid is to be condemned. Patients who have very large, rapidly growing, pedunculated or submucous fibroids, or who have a severe anemia or various other complications, should not be given x-ray treatment. The ideal tumor for radiation is one in the mid-line, smooth, without nodules, without any deviation of the uterine cavity, in a patient forty-five years of age or older but not past the menopause. There are not many fibroids that should be treated radiologically. Most should be treated surgically because of the many other pathologic lesions that are found in the pelvis at operation. Operation is to be preferred if the patient is under forty-five, because then the ovaries may be conserved, if possible, and an abrupt menopause avoided. Patients with bleeding who have passed the menopause should re-

ceive multiple curettages, and if bleeding does not cease, abdominal exploration and hysterectomy should be performed. Fibroids should never be treated with radiation after the menopause, because in most cases some other cause for the bleeding will be found, possibly an ovarian tumor, a carcinoma of the endometrium or some other serious lesion.

Endometriosis. Endometriosis is best treated by surgery. If the lesion is found to be extremely extensive and dissection of the rectum and sigmoid away from the back of the uterus practically impossible, or if there are multiple small intestinal adhesions in the pelvis, it may be well to avoid surgery. The diagnosis should be confirmed by means of biopsy, and x-ray treatment should be given to destroy the function of the ovary. The absence of the ovarian hormone will allow the endometrioma to shrink and atrophy. Radiation may be used in patients with recurrent endometriosis after a conservative operation has been performed.

Leiomyosarcoma. Leiomyosarcoma of the uterus is not satisfactorily treated with x-rays. True, there is evidence that this tumor is sensitive to radiation and will shrink under the influence of the rays, but a cure cannot be expected.

Miscellaneous. The use of x-ray treatment in patients with sterility, amenorrhea and abnormal bleeding has been discussed by Kaplan,¹⁶ Mazer and Baer¹⁷ and Rock et al.¹⁸ In certain patients with amenorrhea due to a persistent follicle cyst that controls the endometrium, destruction of the cyst by moderate doses of x-rays allows other and younger follicles to develop, which after maturing cause menstrual periods to recur. This is a logical method of treating some patients with abnormal menstrual cycles.

X-ray treatment of the pituitary gland to affect

the menstrual cycle in certain cases of dysfunction has not proved satisfactory, and should not be given until more positive evidence of successful results has been presented.

SUMMARY

The present attitude toward x-ray and radium treatment of various gynecologic disorders is presented. Methods of radiation in pelvic disease are reaching their peaks, and it is probable that there will soon be an awakening of interest in surgical procedures as opposed to radiation.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27021

PRESENTATION OF CASE*

A five-month-old female child entered the hospital because of jaundice.

The infant was born at home after an easy, normal delivery. No hemorrhages, skin lesions, or jaundice were noticed at the time of birth. When the child was three days old, slight jaundice was noticed, and at this same time the urine became deep yellow and the stools clay colored. The patient did not appear ill and, so far as is known, there was no fever. She nursed well at the breast. The jaundice persisted unchanged, as did the color characteristics of the stools and urine, until the age of three months. The informant stated that at this time "the whites of the eyes cleared, the stools became yellow, and the urine less dark." Throughout this period her appetite remained good and the weight gain adequate, so that at three months she weighed 10 pounds, 7 ounces, and was eating soft-solid foods. At four months of age, and associated with the eruption of teeth, the jaundice became severer, the stools white, and the urine dark brown. At this time painful urination was first noticed, in that the child cried before the act and ceased immediately afterward. Two weeks before entry the jaundice intensified, and the patient developed a fever of 101 to 102°F. The patient was studied in another hospital and then transferred.

The family history was noncontributory. The mother had had no stillbirths or miscarriages, and four siblings were alive and well. The mother's blood Wassermann test was allegedly negative, and there was no familial history of jaundice.

On examination the patient was a fairly well-developed and well-nourished, deeply jaundiced infant who was acutely and gravely ill. Breathing was rapid and shallow, with an expiratory grunt, but no limitation of chest motion was noted. The skin was deeply jaundiced, without petechiae, and there was good tissue turgor, with fair elasticity. There was a raised, reddish-blue hemangioma approximately 2.5 by 2 cm. in the epigastric region to the left of the midline. A single olive-

sized, soft, discrete lymph node was present in the left axilla, with shotty cervical and inguinal nodes. The head was normal. The scleras and conjunctivas were markedly icteric. There was a profuse, thick, mucopurulent nasal discharge. The lips were dry and moderately pale; the mucous membranes were intact and icteric. The tonsils were reddened, and the posterior pharynx injected. The chest was fairly well developed, with a moderate amount of external beading, but no Harrison's groove. Examination of the lungs showed dullness to percussion at the right base posteriorly, with diminished breath sounds, a prolonged expiratory phase and many fine, crackling inspiratory rales over this area. The heart was enlarged to percussion; the rate was rapid, and the rhythm regular. There was a loud, blowing, systolic murmur heard all over the chest, both anteriorly and posteriorly, but loudest at the apex. The abdomen was greatly protuberant and distended, and the liver was palpable down to the iliac crest, its surface being smooth and firm, and its edge sharp. The spleen was also palpable down to the iliac crest and was slightly firm. The urethral meatus was slightly more posterior than normal, but the genitalia were otherwise normal. The tendon reflexes were hypoactive but equal; there were no meningeal signs.

The temperature was 101.2°F., the pulse 120, and the respirations 46.

Repeated examinations of the urine showed a specific gravity as high as 1.012 with a ++ test for albumin, a positive bile reaction and a persistent pyuria of moderate degree. On one occasion urine culture showed many colon bacilli. Examination of the blood showed a red-cell count of 2,490,000 with a hemoglobin of 52 per cent, and a white-cell count of 29,050 with 78 per cent polymorphonuclears, 19 per cent lymphocytes, 2 per cent monocytes and 1 per cent eosinophils. The red cells were microcytic but hypochromic, with moderate polychromatophilia. Repeated blood examinations gave essentially the same results. The venous clotting time was 8 minutes, the nonprotein nitrogen of the blood serum 43 mg. per 100 cc., the serum proteins 6.4 gm., and the icteric index 150. The carbon dioxide combining power of the blood on one occasion was 40 vol. per cent and on another 75. A lumbar puncture yielded xanthochromic fluid under increased pressure with a + test for globulin, normal sugar, and a total protein of 46 mg. per 100 cc. The fluid contained 52 red cells and 14 white cells per cubic millimeter, 9 of which were polymorphonuclears. There was no growth on culture, and a titration Hinton test in dilutions up to 1:128 was negative.

*This case is presented through the courtesy of the Children's Hospital, Boston

A throat culture on admission yielded many Type 17 pneumococci, and a blood culture grew hemolytic streptococci. Subsequent blood cultures were negative.

During hospitalization the patient ran a septic course, the temperature spiking to 105°F., and shortly after admission sulfathiazole therapy was instituted. The jaundice gradually intensified, and although the feces were usually clay colored, some were dark brown and appeared normal. By the end of the first hospital week the infant developed rather severe diarrhea, so that parenteral fluid therapy was necessary and three blood transfusions were given. The diarrhea increased to such an extent that everything was discontinued by mouth and a constant intravenous drip of aminoacid solution administered. On the fourteenth hospital day, because of microscopic hematuria, sulfathiazole was discontinued and sulfanilamide substituted. The patient died on the seventeenth hospital day. Terminally the nonprotein nitrogen of the blood rose to 68 mg. per 100 cc., and the icteric index to 300; a blood sodium was 158 milliequiv. per liter, and the blood chloride 110 milliequiv. Blood sulfanilamide determinations averaged 8 mg. per 100 cc., with a high of 22 mg. Urine sulfanilamide levels reached 104 mg. per 100 cc.

DIFFERENTIAL DIAGNOSIS

DR. JOHN D. STEWART: I might say at the outset that the most plausible diagnosis in this case is congenital malformation of the bile ducts. However, other possibilities have to be considered briefly.

Icterus neonatorum usually clears up by the end of the second week and is not associated with clay-colored stools or the presence of bile in the urine, and therefore may be dismissed from consideration. In the early history of this case erythroblastosis would have to be considered a definite possibility. However, the protracted five months' course, during which the jaundice was steadily maintained, would, according to my limited knowledge of erythroblastosis, exclude that diagnosis. The enlarged liver and spleen, of course, would go with erythroblastosis, but they would also be compatible with biliary cirrhosis based on prolonged obstruction of the bile flow. There was rather severe anemia, but despite repeated examinations of the blood there is no note that erythroblasts were found in the smear; the red cells were microcytic and hypochromic in type. Furthermore, a secondary anemia might well be found in obstructive jaundice of five months' duration with accompanying infection and malnutri-

tion. The possibility that this might be jaundice on a hemolytic basis need not, in my opinion, be considered seriously. The duration was too long and the jaundice was more or less steady and of the obstructive type, with absence of bile in the stools most of the time and with bile in the urine.

Congenital syphilis has to be considered. It would have been a serious diagnostic possibility at the outset, until excluded by the allegedly negative maternal blood Wassermann test and by the negative Hinton test in the patient's cerebrospinal fluid. The hemangioma that is described at the left of the midline in the epigastrium and the olive-sized lymph node in the left axilla might make one pause for a moment, but I see no reason to suppose from the description of this lesion that it was malignant and might have metastasized and produced obstructive jaundice and enlargement of the liver. I mention it merely in passing. To me, by far the most plausible diagnosis is congenital malformation of the bile ducts. With obstructive jaundice it would certainly be unusual to have a spleen enlarged to the extent that this spleen was. However, I do not believe that should cast too much doubt on the diagnosis. Of course, enlargement of the liver is to be expected.

Interesting points in the clinical course are the fluctuation in the level of jaundice, and the fact that bile was at times excreted into the gastrointestinal tract. The extent of bilirubinemia in any given case depends on several factors. In the first place it depends on the degree of the obstruction to the excretion of bile; secondly, on the rate at which bilirubin is excreted through the kidneys; and, finally, on the rate at which bilirubin is formed. The rate of formation of bilirubin also depends on several factors, such as nutritional intake and whether or not blood transfusions are being given. In a patient with obstructive jaundice and complete blockage of the bile flow, the serum bilirubin level may rise after a blood transfusion. The question comes up as to whether any significant amounts of bile may be excreted through the intestinal mucosa. That has never been to me a very satisfactory theory. In the adult it is safe to say that in the presence of complete obstruction to the bile flow there will be no bile in the stools. This patient may, of course, have had only partial obstruction to the common duct, a stenosis rather than obliteration. If there is stenosis of the bile ducts without complete obliteration, varying degrees of infection and inspissation of the bile and mucus might produce temporary obstruction but not a sustained complete obstruction.

Patients with complete obliteration of the bile

ducts, as shown in a very excellent study made by Ayer,¹ die of two causes, namely, malnutrition and infection. Malnutrition undoubtedly was present in this case, although on the whole I am impressed with the meagerness of the evidence pointing to it. We have a statement that there was more or less normal weight gain at one point in the history, and the physical examination indicated no extensive disturbance of malnutrition at the time the patient entered the hospital. The type of malnutrition particularly to be expected in congenital obstruction to the biliary flow, and also in the adult patient with obstructive jaundice, is interference with the absorption of fat-soluble substances, because fatty substances are taken up in the intestine with the aid of bile salts. Hence vitamin A deficiency would be one of the things to be watched for and also a deficiency of vitamin K and impairment of the clotting mechanism. We have no evidence that there was any particular disturbance in the clotting power, and there is no direct evidence of vitamin A deficiency. However, it is possible that the pathologist at his examination found distinct evidence of vitamin A deficiency in the epithelium of the renal pelvis or in the respiratory mucosa. In connection with the matter of nutrition, it interests me that this patient was treated while in the hospital with parenteral aminoacid therapy, a fact which brings up the question of administering aminoacids or a high protein diet to a patient with liver damage. There has been considerable dispute about it, but there seems to be a growing tendency to ignore the theoretical contraindications and treat patients with liver disease with a high dietary protein allowance.

This patient had sepsis for an indefinite time. There is direct evidence of infection in the urinary tract, and the child without doubt had pyelitis. The possibility that this pyelitis was based on a congenital anomaly of the urinary tract comes to mind. We have no way of deciding that question, but pyelitis in these patients is not uncommon in the absence of obstruction to urine flow. I therefore do not see that we have to postulate an anomaly of the urinary tract. There probably was a bronchopneumonia as a terminal complication. The question of whether there may have been infection in the liver also must be considered. In the reported cases this is unusual, and I see no reason to suspect that there was intra-hepatic infection in this case.

It seems to me that there was not a great deal of evidence of interference with renal function. Protracted obstructive jaundice is often associated with impairment of renal function, but in the

study that Ayer made of the renal tissue in the group of patients dying with congenital obstruction to the bile flow, significant lesions in the kidney, that is, lesions that might be associated with impaired function, were unusual. I am unable to interpret the cerebrospinal-fluid findings in this case. Whether they are related to kernicterus and changes in the brain I cannot say, but I think that is a good possibility. I see no reason to suppose there was meningitis. In conclusion I shall make a diagnosis of congenital malformation of the bile ducts with obstructive jaundice, biliary cirrhosis, pyelitis, a terminal pneumonia and bile nephrosis.

DR. HAROLD L. HIGGINS: I should like to ask Dr. Stewart if he would have explored this child if the case had come to his attention before the final episode.

DR. STEWART: In the material studied at the Children's Hospital, out of 45 cases with congenital obstruction to the flow of bile, 9 were found at operation to have lesions amenable to surgical treatment; therefore, there is a fair chance that surgical cure can be effected if the patient is in a condition warranting operation. There have been a number of patients who have grown to healthy maturity after operation for this condition.

DR. HIGGINS: The terminal episode in this case fits in very well with vitamin A deficiency. Urinary obstruction might result from epithelial debris and lead to the pyelitis. Similar epithelial debris in the bronchi probably lead to the bronchopneumonia, which would have resulted fatally sooner if the patient had not been given sulfathiazole. Treatment with vitamin A parenterally would have been distinctly in order. I should expect that there were pathological findings of rickets; the mention of a rosary is made in the history.

CLINICAL DIAGNOSES

Obstructive jaundice (? congenital atresia of bile ducts).

Bronchopneumonia

DR. STEWART'S DIAGNOSES

Congenital malformation of bile ducts, with obstructive jaundice.

Biliary cirrhosis

Pyelitis.

Terminal pneumonia

Bile nephrosis

ANATOMICAL DIAGNOSES

Bacteremia Type 17 pneumococcus and colon bacillus.

Bronchopneumonia, acute and chronic

Pyelonephritis, mild, chronic (colon bacillus).
 Atresia of extrahepatic biliary system, congenital,
 with agenesis of gall bladder and cystic duct.
 Obstructive biliary cirrhosis.
 Icterus, generalized, severe.
 Annular pancreas.
 Malformation of chordae tendineae to the aortic
 valve, congenital.
 Coarctation of aorta just proximal to ductus
 arteriosus, moderate.

PATHOLOGICAL DISCUSSION

DR. SIDNEY FARBER*: This is a complicated story, and I shall try to divide the findings into several groups. There was widespread infection in the lungs, both acute and chronic in type. That process had been going on for a number of weeks, with some organization of the exudate and a considerable amount of a fresh pneumonic process superimposed on the earlier one. Type 17 pneumococcus was found in the heart's blood at the time of autopsy, and the colon bacillus also. There was a pyelonephritis on the wane at the time of autopsy, so that I think we have every reason for assuming that both organisms had a perfect right to appear in the heart's blood. There was an otitis media with necrosis of the petrous portion of the temporal bone on one side, and a pneumococcus of the same type was cultured from that lesion. So much for the inflammatory changes. There was no evidence of meningitis — only edema and congestion of the brain.

Generalized icterus was present. The cause of this was found in an extensive malformation of the extrahepatic biliary system, which was responsible for obstructive biliary cirrhosis. The liver was considerably increased in size, very firm in consistence and deep green. The fibrosis secondary to the biliary obstruction was widespread enough to account for considerable portal obstruction. The spleen was four times the expected size for this age, and was the seat of considerable chronic passive congestion. There was a moderate degree of coarctation of the aorta just proximal to the ductus arteriosus. A second congenital vascular defect was a malformation of the chordae tendineae to the tricuspid valve, which caused a moderate degree of tricuspid insufficiency. A number of smaller and less important congenital abnormalities were found in various parts of the body.

The two most important abnormalities were the congenital malformation of the bile ducts and an unexpected malformation of the pancreas — an an-

nular pancreas. Both were studied in great detail by Dr. Margaret Huntington, until recently a member of our laboratory staff. The common bile duct was represented by a fibrous cord extending from the junction of similar fibrous hepatic ducts to the ampulla of Vater. At the lower end of the common duct there was a cystlike expansion composed of fibrous tissue without a true lining of epithelial cells. A true lumen was present only in the terminal portion of this common duct, entering into the ampulla of Vater. The cystic duct was also represented by a delicate fibrous cord, which extended to the usual site of the gall bladder. There was no lumen in any portion of this duct or at the site of the gall bladder.

The body and tail of the pancreas were of normal form, but from the head there proceeded a narrow band of pancreatic tissue that encircled the first portion of the duodenum in ring fashion. This ring, which lay just above the ampulla of Vater, produced definite stenosis of the lumen of the duodenum. The main portion of the pancreas drained through the duct of Santorini to open into the first portion of the duodenum just above the pancreatic ring. Into this duct there emptied small channels, which drained the ring portion. A duct of Wirsung could not be found.

There was no histological evidence of vitamin A deficiency. There was, however, a very marked reduction in the amount of vitamin A in the liver, determined according to the method of May and McCreary,² so that we are forced to conclude that there was a deficiency of vitamin A at the time of death. There was evidence of slight rickets on histological examination. Some years ago Dr. Mark Altschule³ studied a series of patients with congenital atresia of the bile ducts in our laboratory, and he found microscopic evidence of vitamin A deficiency in about 50 per cent.

I assume that an exploratory operation was not performed because of the pneumonic process. All patients with this general clinical picture are treated surgically, since surgical re-establishment of the extrahepatic biliary system, when possible, is the only effective treatment.

DR. STEWART: Was there any kernicterus?

DR. FARBER: No; kernicterus is essentially a pathological and not a clinical diagnosis.

A PHYSICIAN: Does a ring-shaped pancreas permit development to adult life?

DR. FARBER: Yes, about 50 cases are on record, and I think it has to be added to that very long list of causes of partial obstruction to the intestinal tract. Another case in an infant has turned up at the Children's Hospital since the one here described.

CASE 27022

PRESENTATION OF CASE

A fifty-eight-year-old man entered the hospital complaining of precordial pain of six and a half hours' duration.

For an unstated period the patient had had slight substernal discomfort on climbing hills. At seven o'clock on the morning of admission he was seized with a severe precordial pain accompanied by a choking sensation. He described the pain as ascending diffusely from the pit of his stomach to his neck and shoulders. It abated somewhat, but four hours later returned in all its severity and radiated down both arms. The patient summoned his physician, who sent him immediately to the hospital.

The patient had had pneumonia eight years previously. The family history was irrelevant.

On examination the patient was well developed and well nourished, restless, and appeared acutely ill. He complained of substernal pain, arm discomfort and nausea. His color was ashen, with cyanosis of the lips and nailbeds. The scleras were clear; the pupils were equal and reacted to light and distance. Examination of the lungs was negative. The heart was enlarged to percussion, and on auscultation the sounds were distant and of poor quality, with a gallop rhythm at the apex. Systolic and diastolic murmurs were heard, loud at the base, faint at the apex. The aortic second sound was greater than the pulmonic. The pulses were equal and synchronous, but of poor quality and tension; the blood pressure was 200 systolic, 96 diastolic, in both arms. Examination of the abdomen was negative. Examination of the nervous system was negative.

The temperature was 98.6°F., the pulse 72, and the respirations 16.

An electrocardiographic recording showed normal rhythm with a rate of 60. There was left bundle branch block, inverted T₁, diphasic T₂ and T₄, and a normal PR interval.

That evening, eleven hours after the first attack of substernal pain, the patient suddenly died.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT E. GLENDY: It is apparent at first glance that we must decide whether this man had

acute coronary thrombosis or whether he had something else. There seems to be little doubt that he did have angina pectoris on effort for an indefinite period before the onset of his acute illness. The description of the initial symptoms of the final episode might, if not subjected to too much scrutiny, be accepted as fairly typical of coronary thrombosis. It is not quite clear from the wording whether the onset of the pain was gradual, with progressive increase in severity, as one might expect with coronary thrombosis, or whether it was very sudden, reaching its maximum intensity quickly, as might be the case in dissecting aneurysm of the aorta. At first the pain radiated only to the neck and shoulder, then abated, and later radiated to the arms. This sequence of events does not seem to be of any particular significance in making a diagnosis of coronary thrombosis, whereas it is possible that if he had dissecting aneurysm the initial pain marked the initial rupture and dissection within the coats of aorta, and the subsequent spread to the arms occurred when the proximal dissection involved one or both of the coronary orifices. The reason I raise this point is that it is rather unusual in dissecting aneurysm to have radiation of pain into the arms except, perhaps, when the coronary circulation has been involved by proximal dissection.

The past history affords no relevant information. Physical examination showed an acutely ill, ashen man with cyanosis of the lips and nailbeds. The degree of collapse described may occur in various cardiovascular emergencies. A blood pressure of 200 systolic, 96 diastolic certainly does not rule out coronary thrombosis, but it is quite against it. Were there any other blood-pressure determinations?

DR. TRACY B. MALLORY: That is all we have.

DR. GLENDY: The high blood pressure suggests the possibility of dissecting aneurysm of the aorta, because in this condition the pressure may be very high, even with an extreme degree of collapse. The negative findings in the lungs are significant, and I think they favor the diagnosis of dissecting aneurysm rather than any serious acute myocardial damage. Both the normal respiratory rate in the absence of dyspnea and orthopnea and the fact that the pulmonic second sound was not abnormal seem to bear this out. The enlargement of the heart certainly affords no etiologic clue, except that perhaps heart disease was present. The distant heart sounds, which were of poor quality, and the gallop rhythm likewise do not offer any important differential features. Incidentally, the term "gallop rhythm" is usually reserved for pulse rates above the normal range, but it is possible, I suppose, for the same mechanism to be in operation

at the slower rates of 72 and 60 when the heart is under considerable strain.

The muffled heart sounds I do not know exactly how to interpret. They may be due to weakening of the myocardium or possibly to an accumulation of fluid, which would undoubtedly, in this case, be blood in the pericardial sac.

The systolic and diastolic murmurs, maximal at the base of the heart, are, I believe, of considerable importance in arriving at a diagnosis. We have no previous history of rheumatic infection or syphilis, and nothing except the murmurs to suggest either of these conditions at this examination. The aortic second sound was described as present and greater than the pulmonic second sound. This certainly seems to be against any marked organic deformity or rigidity of the aortic valve that might be present with rheumatic or syphilitic heart disease.

What else might be responsible for such murmurs? Calcareous aortic-valve disease, possibly; but I think this is unlikely for the same reasons that I have just stated for rheumatic and syphilitic heart disease. The murmurs may have been pericardial in origin if there was fluid accumulating in the pericardial sac. Finally, the murmurs may have been, and I believe were, due to changes occurring in the aortic ring from dissecting aneurysm. We have no previous examination on which to base this conclusion, but such murmurs do appear fairly often in acute dissecting aneurysm owing to altered conditions in the aortic ring, and the mechanism is said to be due to the same factors that produce the murmurs in arteriovenous aneurysm, that is, the usual lumen of the aorta representing one vessel and the dissected portion the other, connected by a slit or rent in the intima.

The examinations of the abdomen and nervous system are reported as negative. There is no mention made of the peripheral pulses in the legs and feet. Do you know whether any observations were made?

DR. MALLORY: None were recorded.

DR. GLENDY: I am not surprised, because several years ago in reviewing 20 cases of dissecting aneurysm the clinical information, particularly in regard to peripheral pulsations, was very meager. I think that was largely due to the fact that when such a patient came in he was so ill that the doctors did not examine him completely, postponing it until a later time, which never came because the patient died. These people do not linger long.

The electrocardiogram showed left bundle-branch block, indicating coronary disease, but the disturbances in the T waves might occur with block alone, and I do not believe that there is any-

thing in the tracing to indicate an acute myocardial process; this, again, would be against coronary thrombosis. I believe that this man had hypertensive coronary heart disease with cardiac enlargement, angina pectoris, and an acute dissecting aortic aneurysm, with at least proximal dissection and possibly distal dissection, the former involving the mouths of the coronary vessels; his sudden death was probably the result of rupture of this aneurysm into the pericardial sac or the mediastinum.

DR. MALLORY: Are there any alternative suggestions? Dr. Glendy has made his case very convincing.

DR. MILTON H. CLIFFORD: I can add nothing to the history. Very little could be found out about the past. The patient had seen a physician about six years before admission, but unfortunately no record of the blood pressure was made. The patient had always felt very well. When first seen he was not in any particularly acute shock, although a bit ashen. The blood pressure at that time was 170 systolic, 80 diastolic. It is evident that the shock must have increased greatly by the time he reached the hospital.

DR. PAUL D. WHITE: Dr. Mallory has handed me the electrocardiograms, and as Dr. Glendy stated, there is no evidence of any massive myocardial involvement, simply that of coronary heart disease, a clear-cut, well-marked left bundle-branch block, with T waves and ST segments in keeping with chronic coronary disease. There may be a normal-appearing electrocardiogram in the three clinical leads in the first few hours or days of coronary thrombosis, although there usually is an early change. If there had been massive enough myocardial involvement to kill the patient so quickly, one would expect more change.

DR. WILLIAM B. BREED: Is there anything in the electrocardiogram to suggest massive pulmonary infarction?

DR. WHITE: With bundle-branch block it may be impossible to detect complications. One cannot tell so much about what is going on as in normal complexes because the QRS and T waves in bundle-branch block are already greatly deformed. I cannot answer with certainty, but I should expect some change in the T waves, even in the presence of bundle-branch block, if massive pulmonary infarction were present. We have not, however, happened to encounter such a combination.

DR. BREED: With the story of pain in the chest, in spite of the negative chest examination at entrance, one must bring up the question of pulmonary embolism although I do not believe one can be definite. It should be considered.

DR. ROBERT S. PALMER: Rarely also one sees rup-

ture of the heart after coronary thrombosis. When would such rupture take place?

DR. WHITE: In going over a series of autopsies a few years ago we found that the average time of rupture of the heart after infarction was on the sixth day; of 16 cases, it occurred before the sixth day in 6, on the sixth day in 4, and after the sixth day in 6.

DR. EDWARD F. BLAND: We had 1 case in which it occurred in four or five days.

DR. WHITE: Have we seen any rupture within twenty-four hours, Dr. Mallory?

DR. MALLORY: I remember one that occurred in forty-eight hours. I think it has been reported within twenty-four.

CLINICAL DIAGNOSES

Coronary occlusion.

Myocardial infarction.

DR. GLENDY'S DIAGNOSES

Hypertensive, coronary heart disease.

Cardiac hypertrophy.

Angina pectoris.

Dissecting aneurysm of the aorta, with proximal dissection involving the coronary orifices and rupture into the pericardium or mediastinum

ANATOMICAL DIAGNOSES

Dissecting aneurysm of ascending aorta, with rupture.

Media necrosis cystica aortica.

Hemopericardium.

Cardiac hypertrophy.

Pheochromocytoma of the adrenal gland.

Nephrosclerosis.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The post-mortem examination confirms Dr. Glendy's predictions. There was a dissecting aneurysm of rather short extent. A horizontal tear was found in the intima of the aorta about 2 cm. above the aortic valve. There was dissection backward to the annulus fibrosus and the mouths of the coronary arteries, and forward as far as the arch of the aorta, where it stopped abruptly. There was no dissection of the

abdominal or thoracic aorta. The aneurysm had ruptured externally into the pericardium, and since nearly 700 cc. of blood was present in the pericardial sac, it is reasonable to assume that the immediate mechanism of death was cardiac tamponade. The points of internal and external rupture were very near to each other.

DR. WHITE: Was the arch calcified?

DR. MALLORY: Yes; there was some calcification.

DR. WHITE: I wonder if the calcification stopped further dissection.

DR. MALLORY: It was limited to the intima, and since the plane of dissection was in the media, I should not think so.

DR. WHITE: I was thinking of the case that we saw last year with a rigid descending aorta, senile ectasia and a dissecting aneurysm of the ascending aorta; it was difficult or impossible for the dissection to continue down to the abdominal aorta.

DR. MALLORY: Occasionally in the abdominal aorta, calcification does extend deeply into the media and therefore might block dissection. In sections from most of this aorta there was no evidence of media necrosis cystica, but in the ascending aorta, the region of the dissection, there was clear evidence of it. I think that the dissection was limited to the portion of the aorta involved by the media necrosis cystica. There was considerable cardiac hypertrophy,—the heart weighed 550 gm,—which would suggest that the hypertension had been present for a significant period of time. The coronary arteries and the aortic valve were entirely normal.

One complete surprise of the autopsy was a tumor of the adrenal gland, centrally placed and small—about 1 cm. in diameter. This was a pheochromocytoma and may or may not have been responsible for the hypertension. There was also an ordinary nephrosclerosis.

DR. WHITE: You say that the coronary arteries were normal. I suppose there must have been some involvement of the smaller branches, unless this bundle-branch block could be attributed to an old infectious process, which would be much less likely.

DR. MALLORY: There was no gross involvement of the coronary arteries

THE MOST ANCIENT OF THE HEALING ARTS

AN Egyptian sculpture depicts King Akh-en-Aton and Queen Nefertiti (1375-1358 B. C.) holding out their children to be blessed by the healing hands of the Sun God. The king was one of the earliest Monotheists, and his god was the sun. Two thousand years before medicine could be called a science by any stretch of the imagination, physical therapy was being successfully employed by the Egyptians. In recent years there has been great change and advance in the methods and agents used in the treatment of many different diseases and lesions. The applicability and worth of physical therapy in many disorders seem to have been so forgotten by the regular school of medicine that its practice is becoming associated with

certain cults. This situation is unfortunate for medicine and for its charges.

The prescription and administration of physical therapy are not the prerogatives of any specialty; they belong to general medicine. Physical therapy is as important in the treatment of cardiovascular diseases, disorders of the endocrine glands and chronic arthritic diseases as it is in neural disorders and orthopedic conditions. It is one of the most effective weapons of preventive medicine; it is the universal stimulator of convalescence. Thirty per cent of our countrymen drafted in World War I were rejected because of physical defects—and without doubt a still higher figure would hold true among women. The same percentage is anticipated, and, indeed, is being found, in the present conscription. Because the rehabilitating powers of physical therapy were demonstrated beyond cavil in the last war, it is safe to say that this disquieting number would be cut in halves if the medical profession could "sell" to American youth the simple prescriptions of preventive physical therapy.

What shall we do about the existing neglect of this most ancient art of healing? With his usual acuity Dr. Alan Gregg,* of the Rockefeller Foundation, has touched the sorest spot in the present situation: "A curious phenomenon in American medicine is the deft elimination of much reference to physical therapy, mindful, I suppose of the abuses imputed to osteopaths and chiropractors. . . . Thus protected our graduates angrily complain of competition from those whose knowledge it is tabu to acquire. The current unabashed ignorance of physical therapy in the country leaves it an excellent opportunity for development in American medicine." Dr. Gregg is correct—the fault lies in the medical schools. The first-rate schools are as guilty, if not guiltier, than the poor ones. With a few exceptions, hospital clinics of physical therapy are travesties on the name. Medical education is the heart of medicine, and physical therapy represents an essential artery of health. Can we not prevent it from becoming sclerotic?

*Gregg, A. Addenda to the agenda for the decade 1940-1950. *J. A. M. A.* 114:1139-1141, 1940.

There are a few voices crying in this wilderness of neglect. The Council on Physical Therapy of the American Medical Association is the loudest and most effective, but thus far the practical results have been meager except for hindering the sale of expensive and largely valueless apparatus to physicians in general practice. There is the "still small voice" of the Committee on Physical Therapy of the Massachusetts Medical Society, but physicians have turned an almost deaf ear to the five-year-old proddings of the committee and its offerings of postgraduate courses, exhibits and demonstrations. The medical schools, if they will, can convince their students of the importance of physical therapy and can provide the most efficient "hearing aid" for their graduates. This is one branch of medicine in the United States the rank and accomplishment of which compare most unfavorably with its dignity and effectiveness in other countries. "The sense of sin is the starting point of progress." It is high time we started.

It is a satisfaction to report that the Harvard Medical School, in co-operation with the Massachusetts General Hospital, has already taken steps to improve the teaching of physical therapy by the appointment of a medical physiotherapist as an assistant in medicine; he is also in charge of the newly equipped Department of Physical Therapy at the Massachusetts General Hospital.

THE MODERN DRUGSTORE

In a recent number of *Hygeia* appears an article that is heartening in indicating the increasing educational requirements and competence of professional pharmacists. The marketing of prescriptions to the laity is still a function of the so-called "drugstore," which, in reality, has become a department store. A survey of the prescription business, recently made, tabulates the returns received from 345 drugstores, distributed in such a way as to make an adequate sample of the country. In 1939, less than twelve per cent of the total revenue in these stores came from prescriptions. The average price for prescriptions was 91 cents each; the outlay for other items averaged 30 cents each. The former did not include the many pur-

chases of medicines not made on prescription, and their high unit cost is probably one reason for the appalling amount of self-medication that goes on.

Presumably the cost of the prescription could be somewhat reduced by an increase in volume, since this is accompanied by an increase in prescription stock that is far less than that of the prescription sales. Furthermore, if one classifies the stores, either geographically or in relation to the size of the towns in which they are located, it appears that adequate profits are available to the drugstore regardless of these factors. It is apparent from the above-mentioned analysis that an increased use of prescriptions by doctors would make it possible to reduce their cost.

We, as doctors, are partly to blame for this situation. For a small temporary saving to the patient, we tell him "to buy a bottle of aspirin" or "to get some quinine." To be sure, it would cost the patient more if we wrote a prescription for these things until the practice was so general, and the volume of prescription business so large, that the pharmacist could afford to do away with the department-store end of his business. However, the basic difficulty lies with neither the pharmacist nor the doctor but primarily with the public. One pharmacist, who does a large prescription business, states that many of his regular clients demanded that he put in a lunch counter and soda fountain so that they would have something to do while waiting for their prescriptions to be filled. He finally succumbed, with great profit to himself.

The great problem of modern economics is that of distribution. We have attacked quality, advertising and production fairly successfully, but the problem of distribution remains to be solved in pharmacy as in many other spheres of merchandising.

MEDICAL EPONYM

FOWLER'S SOLUTION

Fowler's Solution owes its name to Thomas Fowler (1736-1801), who in 1786 published an essay entitled "Medical reports of the effects of arsenic in the cure of agues, remitting fevers and periodic headaches." This was printed by J. John-

son, of London, in 1786. In his preface, the author, after calling attention to the fact that a patent medicine—Tasteless Ague and Fever Drops—had acquired some reputation in the country and had been found efficacious, says:

In the Beginning of October, 1783, Mr. Hughes, the Apothecary to the Infirmary, (whose Industry, Attention and Abilities in his professional Line, justly merit Applause) informed the Author, that he had tried to imitate the Ague Drops, and, from a number of Experiments, had so far succeeded (his Medicine having produced similar Effects) that he was convinced they were a Preparation of Arsenic.

In Consequence of this general Intimation, the Author of these Sheets consulted Lewis's Materia Medica upon Arsenic, and agreeable to his pharmaceutic History of that Article, he dissolved a small Portion of the white Sort in a Solution of the fixed vegetable Alkali. On trying and comparing the Effects of this Solution, with those of the Patent Ague Drops, he found the Medicine to be similar, but that the former was too Strong: he therefore diluted the Solution, by doubling the Proportion of Water, and then comparing their Effects, found the Medicines nearly of an equal Strength.

COARCTATION OF THE AORTA IN PREGNANCY

Mrs. M. T., a thirty-two-year-old primipara, was seen on August 9, 1932, in the first month of pregnancy.

The family history was unimportant. The patient gave a history of scarlet fever, measles, pneumonia and mumps in childhood. She had had no serious illness after fifteen years of age. Four or five years before examination she had a period of excessive fatigue, when she was put to bed to rest for a week or two. At this time the systolic blood pressure was found to be 180, but it had not been taken since. Catamenia began at fourteen, were regular with a twenty-eight-day cycle and lasted about four days. The last period began on June 28, making the expected date of confinement April 4, 1933.

At the time of the first examination the patient had no symptoms. General physical examination was negative except for a systolic blood pres-

sure of 170 and a loud blowing systolic murmur, loudest at the base. The urine was normal. The patient was referred at once to a cardiologist, whose opinion was as follows:

The blood pressure is 180 systolic, 100 diastolic, in the arms; the arteries in the legs are barely palpable, and the pulsations so faint that I cannot take the pressure by ordinary measures. The heart has a very loud systolic murmur, loudest at the base, where it is transmitted upward; it can be heard very clearly down the back. These findings are associable with a congenital malformation in the aorta somewhere below the point where the left subclavian comes off. The abbreviated diagnosis is coarctation of the aorta, but I think the trouble is further down the aorta than this diagnosis strictly suggests. The x-ray examination is somewhat unsatisfactory because the patient is so young that the arteries do not show clearly. Nevertheless, the films show a change in the outline of the descending aorta. There is no evidence of nephritis or other disease.

Of course, no one knows what influence this condition may have on pregnancy. There is justification, however, in treating the case as one would a Class I cardiac patient. I have therefore prescribed the usual regime, and asked her to report at regular intervals.

The only thing that enters my mind is the possibility that the pregnancy may be interfered with because of the abnormally low blood supply to the lower part of the body, which might interfere with the development of the fetus. Pregnancy is supposed to be rare among patients with coarctation of the aorta because their bodies are ill nourished below the point of narrowing and their internal genitalia may be poorly developed. But this patient, unlike many of those with coarctation of the aorta, seems to be symmetrically developed.

From this time on the patient was kept under close observation by both the obstetrician and the cardiologist, and her activities were restricted exactly as if she had been a Class I cardiac patient. The pregnancy progressed uneventfully until December 30, when she reported that she had not felt any fetal motion for a week. The uterus was the size of a six and a half months' pregnancy, there appeared to be an excess of fluid, and no fetal heart could be heard. X-ray examination showed a moderate hydramnios and a probably dead fetus. From this time on the uterus did not enlarge, and on March 9 the patient went into labor and delivered a stillborn, macerated fetus. There was no obvious cause for the intrauterine fetal death. The blood pressure had been persistently elevated throughout the pregnancy, at times being 200 systolic. The puerperium was uncomplicated.

Ten months later the patient became pregnant for the second time. She was again kept under close observation by the cardiologist and treated as a patient with organic heart disease. The pregnancy was entirely uneventful; the patient went into spontaneous labor at term and was delivered normally of a baby boy weighing 9 pounds,

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

11 ounces. The convalescence was uncomplicated. About two and a half years later the patient became pregnant for the third time, and again went through her pregnancy without complications and was delivered normally at term of a baby girl weighing 7 pounds, 3 ounces.

At the present time, four years later, this patient is forty years old, is in the eighth month of her fourth pregnancy, has a systolic blood pressure of 170 or 180 but is otherwise entirely well. She has been kept on the same cardiac regime as in the other pregnancies, and a normal termination of the pregnancy is expected.

Comment. This case is reported because of its rarity and to show that coarctation of the aorta in no way contraindicates pregnancy or pelvic delivery.

MEDICAL-COSTS INSURANCE

To The Editor. The following correspondence will undoubtedly be of interest to the members of the Massachusetts Medical Society.

WALTER G PHIPPEN, M.D.

* * *

Dear Dr. Phippen

Following the publication in the *New England Journal of Medicine* of the votes of the Council of the Massachusetts Medical Society in regard to the development of a prepayment insurance plan to cover the costs of medical care, individual members of the Society and the lay press reached the erroneous conclusion that the Society was endeavoring to develop control over all medical service plans.

Since then the lay press has frequently asked the White Cross and Medical and Surgical Associates if there was a conflict between the Massachusetts Medical Society and the White Cross. Both the organizations asked have taken pains to make it clear to the press that although the preliminary synopsis approved by the Council might be given a monopolistic interpretation and suggest a conflict, they were sure that any ambiguity which appeared in the preliminary synopsis would be eliminated in the final draft.

Despite this, articles have appeared several times in the lay press suggesting that there would be a conflict between the Massachusetts Medical Society and other groups that offer medical service on a prepayment basis. The most recent one noted by us appeared in the *Quincy Tribune*. All such articles seem to us to be very unfortunate, and we fear that they may interfere with the development of constructive plans for the delivery of medical service on a prepayment basis.

We can assure you that neither the White Cross nor Medical and Surgical Associates has instigated or authorized anyone connected with the management of either to prepare such an article. Furthermore, we believe that several plans should be developed for the delivery of medical care on a prepayment basis, so that by trial and error the best plan or plans for the public welfare may be secured.

We fear that suspicion still exists in some quarters that the Massachusetts Medical Society is endeavoring to create a monopoly, and we respectfully suggest that you make an announcement in the *Journal* similar to the one which you have made to one of us personally, namely, that the Society has no idea of trying to establish a monopoly.

As a step toward clarifying the situation and eliminating unfounded suspicions we shall be glad to have you publish this letter in the *New England Journal of Medicine*.

Sincerely yours,

Channing Frothingham, *Chairman*,
MEDICAL AND SURGICAL ASSOCIATES

73 Tremont Street,
Boston

Dear Dr. Frothingham

Your letter of recent date is at hand. Inasmuch as several members of the Society have written me in regard to the appearance of articles in the lay press concerning prepayment plans for medical care, I am very glad to publish your letter disclaiming responsibility for these unfortunate publications.

May I take this opportunity to say what has been said before, namely, that the draft of the enabling act presented by Dr. Lanman's committee was merely a preliminary draft. You may remember that I asked that no action be taken by the Council but that the committee desired constructive criticism. The criticisms so received have been duly considered by the committee and will be presented at the next meeting of the Council in February.

So far as we have been able to determine from legal counsel of the Massachusetts Medical Society, our bill does not interfere with any existing plan. The Massachusetts Medical Society believes that any plan that it sponsors should comply with the laws governing insurance in Massachusetts and that it have supervisory control through properly appointed general and local committees of any plan so established. I am sure it does not contemplate a monopoly.

Very sincerely,

Walter G. Phippen, *President*,
MASSACHUSETTS MEDICAL SOCIETY

31 Chestnut Street,
Salem, Massachusetts

MEDICAL POSTGRADUATE EXTENSION COURSES

The following sessions, given by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, have been arranged for the week beginning January 12.

MIDDLESEX EAST

Tuesday, January 14, at 4 15 p.m., at the Melrose Hospital, Melrose. The Clinical Recognition of the Types of Jaundice and Recent Advances in Their Treatment. Instructor Franz Ingelfinger. Walter H. Flanders, *Chairman*.

MIDDLESEX SOUTH

Tuesday, January 14, at 4 00 p.m., at the Cambridge Hospital, Mt. Auburn Street, Cambridge. Pediatric Case Discussions. Instructor Warren R. Sisson. Dudley Merrill, *Chairman*.

NORFOLK

Thursday, January 16, at 8:30 p.m., at the Norwood Hospital, Norwood. Dermatitis and Eczema. Instructor: Bernard Appel. Hugo B. C. Riemer, *Chairman*.

NORFOLK SOUTH

Monday, January 13, at 8:30 p.m., at the Quincy City Hospital, Quincy. Diagnosis and Treatment of Minor Lesions of Rectum and Anus. Instructor: Franklin G. Balch, Jr. David L. Belding, *Chairman*.

SUFFOLK

Thursday, January 16, at 4:30 p.m., in John Ware Hall, Boston Medical Library. Therapeutic Uses of Preparations of Endocrine Glands: Thyroid gland, pituitary gland, ovary, testis and adrenal cortex. Instructor: William T. Salter. Reginald Fitz, *Chairman*.

DEATHS

CRAWFORD — JOSEPH W. CRAWFORD, M.D., of North Adams, died November 7. He was in his sixty-ninth year.

Dr. Crawford received his degree from the Hahnemann Medical College and Hospital of Philadelphia in 1900. He was a fellow of the Massachusetts Medical Society and the American Medical Association, and also held membership in the Radiological Society of North America. He was on the staff of the North Adams Hospital.

CURRAN — CHARLES H. CURRAN, M.D., of Springfield, died September 10. He was in his fifty-first year.

Dr. Curran received his degree from the University of the City of New York Medical Department in 1886. He was a former member of the Massachusetts Medical Society.

FITZPATRICK — FRANCIS J. FITZPATRICK, M.D., of Somerville, died January 2. He was in his sixtieth year.

Born in Charlestown, he attended Boston College and received his degree from the College of Physicians and Surgeons in Boston in 1928. Dr. Fitzpatrick was a member of the Somerville Board of Public Welfare at the time of his death. He was a member of the Massachusetts Medical Society and the American Medical Association.

PAGE — JOSEPH G. E. PAGE, M.D., of Southbridge, died December 28. He was in his seventieth year.

Born in Soral, Quebec, he attended St. Hyacinthe College and Laval University, Quebec, and received his degree from the University of Montreal Faculty of Medicine in 1895. He served as a member of the Southbridge Board of Health for a number of years and was formerly associate medical examiner of that district. Dr. Page was a member of the Massachusetts Medical Society and of the American Medical Association.

His widow, a son, a daughter and a grandchild survive him.

MISCELLANY

GREATER BOSTON COMMUNITY FUND

Dr. Earle M. Chapman will head the Physicians' Group of the Professional Division of Industry and Finance in the Greater Boston Community Fund's 1941 Campaign to raise \$4,883,000 between January 18 and February 5.

The ten committees, each under the direction of a vice-chairman, are composed as follows:

P. C. Baird, vice-chairman. Committeemen: A. G. Brailey, R. W. Daffinee, R. E. Fleming, Ashton Graybiel, E. P. Hayden, W. F. Lever, W. J. Macdonald, Sylvester McGinn, A. S. Rose, Charles Short, O. S. Staples, S. H. Sturgis.

J. M. Baty, vice-chairman. Committeemen: R. C. Eley, M. N. Fulton, Harold Freedman, Theodore Bennett.

Walter Bauer, vice-chairman. Committeemen: Ralph Adams, Henry Beecher, Oliver Cope, Reed Harwood, Carroll Larson, Alfred Ludwig, Champ Lyons, John Stewart, Hans Waite, J. W. Zeller.

Virgil Casten, vice-chairman. Committeemen: Thomas Cavanaugh, E. M. Holmes, G. L. Sullivan, D. A. Thom.

M. H. Clifford, vice-chairman. Committeemen: W. E. Garrey, Earle Glendy, Benjamin Huntington, Donald MacCollum, Harvey Morrison, John Richardson, Francis Rouillard, Thomas Warthin, Claude Welch.

Christopher Duncan, vice-chairman. Committeemen: Alexander Aitken, A. J. A. Campbell, H. C. Donahue, P. R. Johnson, A. Y. Kevorkian, W. F. Leadbetter, George Lynch, C. M. Peters.

Sidney Graves, vice-chairman. Committeemen: R. H. Barker, Arthur Hertig, J. P. Hubbard, M. V. Kappius, S. B. Kirkwood, J. A. Reidy, G. P. Sturgis, V. P. Williams, P. A. Younge, J. L. Newell.

W. I. Gregg, vice-chairman. Committeemen: Herbert Adams, J. S. Mansfield, R. B. Miller, H. I. Suby, Richard Warren.

H. E. Kennard, vice-chairman. Committeemen: Bradford Cannon, Richard Dwight, J. A. Holmes, S. B. Kelley, G. D. Krumbhaar, J. P. Monks, J. B. Sears, Arnold Starr, C. F. Walcott, G. P. Whitelaw.

Jacob Lerman, vice-chairman. Committeemen: Saul Berman, E. E. Covitz, Samuel Hanflig, Mark Lesses, Louis Nathan, Samuel Robins.

Maurice Strauss, vice-chairman. Committeemen: F. G. Balch, Jr., J. M. Faulkner, T. H. Ham, J. C. Harberson, W. P. Murphy, W. R. Ohler, G. C. Prather, H. H. Rosenfield, C. P. Sheldon.

The Hospital Group of the Institutions' Division of Industry and Finance is headed by Dr. Norbert A. Wilhelm, superintendent of the Peter Bent Brigham Hospital. He will be assisted by over a hundred physicians who are members of the hospital staffs of Greater Boston.

CORRESPONDENCE

STATE MENTAL HOSPITALS, LISTED
ACCORDING TO CITIES AND TOWNS

To the Editor: Following is a list of the cities and towns within the Commonwealth; opposite the name of each is indicated the mental hospital to which patients suffering from psychosis should be referred whenever hospitalization becomes necessary. The list is derived from a revision of hospital districts within the State which became effective October 1, 1940, and was necessitated chiefly by the fact that certain hospitals were receiving a greater number of admissions than could be properly accommodated.

Committing courts were advised of the change at the time. It now appears, however, that the information has not reached many physicians in the Commonwealth.

CLIFTON T. PERKINS, *Commissioner,*
Department of Mental Health.

100 Nashua Street, Boston.

RESTORATION OF LICENSE

To the Editor: The license of Dr. Anthony P. Carogana, 672 Broadway, Chelsea, Massachusetts, which was revoked on July 11, 1940, was restored by the Board of Registration in Medicine on December 19, 1940.

STEPHEN RUSHMORE, M.D., *Secretary,*
Board of Registration in Medicine.

State House,
Boston.

NOTICES

WILLIAM HARVEY SOCIETY

There will be a lecture on "Relation of the Internal Secretions to Cancer" by Dr. Joseph C. Aub, sponsored by the William Harvey Society of the Tufts College Medical School, on Friday, January 17, at 8 p.m., in the auditorium

of the Beth Israel Hospital Dr S J Thannhauser will be chairman of the meeting

All interested members of the medical profession are cordially invited

BOSTON SOCIETY OF BIOLOGISTS

There will be a meeting of the Boston Society of Biologists in the Ether Dome of the Massachusetts General Hospital on Wednesday, January 22, at 8 p.m. Dinner will be served in the dining room of the hospital at 7 p.m.

PROGRAM

Vitamin A Absorption Curves Drs John McCreary and Charles May

Vitamin A and Night Blindness A laboratory and field study Dr George Wald

Disproportionate Growth of Skeleton and Central Nervous System in Young Animals in Vitamin A Deficiency Drs S B Wolbach and O A Bessey

BOSTON LYING IN HOSPITAL

There will be a meeting of the Journal Club of the Boston Lying in Hospital on Wednesday, January 15, at 8 15 p.m. Dr. Richard D. Bryant, of the Department of Obstetrics, Cincinnati General Hospital, will speak on "Treatment of Eclampsia by Veratrum Viride"

BOSTON DOCTORS' SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will rehearse under Alexander Thuede, formerly concert master of the Cleveland Symphony Orchestra, every Thursday at 8 30 p.m. Those interested in becoming members should communicate with Dr Julius Loman, Pelham Hall Hotel, Brookline (BEA 2430)

JEWISH MEMORIAL HOSPITAL

A meeting of the staff of the Jewish Memorial Hospital will take place on Thursday, January 16, in the hospital auditorium, 45 Townsend Street, Roxbury, at 8 30 p.m. Dr Samuel A Levine will speak on "Some Important Errors in the Diagnosis of Heart Disease"

All interested physicians are cordially invited to attend

HARVARD MEDICAL SOCIETY

There will be a meeting of the Harvard Medical Society on Tuesday, January 14, in the amphitheater of the Peter Bent Brigham Hospital at 8 15 p.m. Dr A Rosenbluth will speak on "A Physiological Analysis of Abnormal Neuromuscular Function"

CUTLER LECTURE

Dr Henrik Dam, associate professor at the Biological Institute, University of Copenhagen, will give the Cutler Lecture on Preventive Medicine at the Harvard Medical School on Thursday, January 30. His subject will be Vitamin K. Its general significance in biochemistry, and its role in human pathology and its application in therapeutics, and the lecture will begin at five o'clock in the amphitheater of Building E. These lectures have been

given annually since 1912. The medical profession, medical and public health students and others interested are invited to attend

NEW ENGLAND WOMEN'S MEDICAL SOCIETY

The annual meeting of the New England Women's Medical Society will be held at the Myles Standish Hotel on Thursday, January 16. A business meeting will be held at 6 30 p.m. followed by dinner at 7 15 p.m. Dr Elbott P Joslin will speak on "My Present Interest in Diabetes"

NEW ENGLAND PATHOLOGICAL SOCIETY

The next meeting of the New England Pathological Society will be held at the Beth Israel Hospital on Thursday, January 16, at 8 p.m.

PROGRAM

March Hemoglobinuria Dr D R Gilligan

Intestinal Obstruction Dr Jacob Fine

Incidence and Distribution of Coronary Artery Occlusions Dr M J Schlesinger

Business meeting

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held at the Peter Bent Brigham Hospital on Monday, January 27, at 8 15 p.m.

PROGRAM

Pulmonary Congestion and Edema in Heart Disease With special reference to the interpretation of roentgenological findings Dr Soma Weiss

The Picture of Shock in Heart Disease Drs Richard V Ebert and L A Stead, Jr

The Prognosis of Right Bundle Branch Block Drs George Perera and Herman Erlanger

Observations on the Circulation in Some Forms of Congenital Heart Disease Drs E C Eppinger, Robert E. Gross and C Sidney Burwell

The Effect of Flow of Blood in Small Vessels on Hematocrit Reading Drs E A Stead, Jr, and Richard V Ebert

The Wolff-Parkinson-White Syndrome with Attacks of Ventricular Tachycardia Drs S A Levine and Paul B Beeson

Interested physicians and medical students are cordially invited to attend

VAN METER PRIZE AWARD

The American Association for the Study of Goiter again offers the Van Meter Prize Award of three hundred dollars and two honorable mentions for the best essays submitted concerning original work on problems related to the thyroid gland. The award will be made at the annual meeting of the association, which will be held at Boston, Massachusetts, on May 26, 27 and 28, provided essays of sufficient merit are presented in competition.

The competing essays may cover either clinical or research investigations should not exceed three thousand words and must be presented in English, a typewritten double spaced copy should be sent to the corresponding secretary, Dr W Blair Mosser, 133 Biddle Street, Kane, Pennsylvania, not later than April 1.

A place will be reserved on the program of the annual meeting for presentation of the prize-award essay by the author, if it is possible for him to attend. The essay will be published in the *Proceedings* of the Association. This will not prevent its further publication, however, in any journal selected by the author.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, JANUARY 12

SUNDAY, JANUARY 12

- †4 p.m. Hormones and Children. Dr. Joseph C. Aub. Free public lecture. Harvard Medical School, Building D.
- †4 p.m. What About Cancer? Dr. W. Stewart Whittemore. Public health lecture. Cambridge Hospital, Margaret Jewett Hall.

MONDAY, JANUARY 13

- 12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

TUESDAY, JANUARY 14

- *9-10 a.m. Intestinal Intubation. Dr. Louis Zetzel. Joseph H. Pratt Diagnostic Hospital.
- 12:15-1:15 p.m. Clinicoröntgenological conference. Peter Bent Brigham Hospital amphitheater.
- 8:15 p.m. A Physiological Analysis of Abnormal Neuromuscular Function. Dr. A. Rosenbluth. Harvard Medical Society. Amphitheater, Peter Bent Brigham Hospital.

WEDNESDAY, JANUARY 15

- *9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.
- *12 m. Clinicopathological conference. Children's Hospital.
- *2-4 p.m. Dyspnea and Cough. Drs. C. S. Burwell and Robert Gross. Peter Bent Brigham Hospital.
- 8:15 p.m. Treatment of Eclampsia by Veratrum Viride. Dr. Richard D. Bryant. Journal Club, Boston Lying-in Hospital.

THURSDAY, JANUARY 16

- *8:30 a.m. Combined clinic of the medical, surgical, orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital, at the Peter Bent Brigham Hospital.
- *9-10 a.m. Chorioepithelioma. Dr. J. T. Smith. Joseph H. Pratt Diagnostic Hospital.
- 6:30 p.m. New England Women's Medical Society. Myles Standish Hotel, Boston.
- 8 p.m. New England Pathological Society. Beth Israel Hospital, Boston.
- *8:15 p.m. Surgery of the Chest. Dr. Edward D. Churchill. United States Naval Hospital, Chelsea.
- 8:30 p.m. Some Important Errors in the Diagnosis of Heart Disease. Dr. Samuel A. Levine. Jewish Memorial Hospital.

FRIDAY, JANUARY 17

- *9-10 a.m. The Present Status of Pneumonia Therapy. Dr. Maxwell Finland. Joseph H. Pratt Diagnostic Hospital.
- *8 p.m. Relation of the Internal Secretions to Cancer. Dr. Joseph C. Aub. William Harvey Society. Auditorium, Beth Israel Hospital, Boston.

SATURDAY, JANUARY 18

- *9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.

*Open to the medical profession.

†Open to the public.

APRIL 30 — Page 604, issue of October 10.

WORCESTER

FEBRUARY 12 — Worcester State Hospital, Worcester.

MARCH 12 — Memorial Hospital, Worcester.

APRIL 9 — Hahnemann Hospital, Worcester.

Supper at 6:30 p.m. followed by a business meeting and scientific program.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Life of Sir William Osler. By Harvey Cushing, M.D. 8°, cloth, 1417 pp., with 10 illustrations. New York: Oxford University Press, 1940. \$5.00.

Surgical Anatomy of the Head and Neck. By John F. Barnhill, M.D., LL.D., formerly professor of otolaryngology, Indiana University School of Medicine, emeritus professor of surgery of the head and neck, formerly chief of the Department of Head and Neck Surgery, Indiana University Hospitals, and honorary professor of anatomy, University of Southern California School of Medicine; and William J. Mellinger, M.D., associate professor of anatomy, University of Southern California School of Medicine, chief of Department of Eye, Ear, Nose and Throat, Cottage Hospital, Santa Barbara, and otolaryngologist, Santa Barbara General and St. Francis hospitals. Introduction by Paul S. McKibben, professor of anatomy, University of Southern California School of Medicine. Second edition, rearranged and revised. 4°, cloth, 773 pp., with 431 illustrations. Baltimore: Williams & Wilkins Company, 1940. \$15.00.

Diagnosis and Treatment of Arthritis and Allied Disorders. By H. M. Margolis, M.D., M.S. (in med.), chief, Arthritis Service, St. Margaret Memorial Hospital, associate in medicine, Montefiore Hospital, and consultant in medicine, Pittsburgh Diagnostic Clinic. 8°, cloth, 551 pp., with 140 illustrations. New York: Paul B. Hoeber, Incorporated, 1940. \$7.50.

NUMBER 3

WHITHER AMERICAN OBSTETRICS?^{*}

NICHOLSON J. EASTMAN, M.D.†

BALTIMORE

I SHOULD be most remiss if I did not acknowledge at the outset my deep appreciation of the honor accorded me by your invitation to speak here on Walter Channing Day, at this Founders' Day meeting of the Boston Lying-in Hospital, an institution that has so long exemplified the finest traditions of American obstetrics, and the annals of which are so rich in contributions of the first order. But my gratification at being here is based not only on these circumstances, but is attributable in no small measure to another consideration. I refer to the close and pleasant relation that exists between the Boston Lying-in Hospital and our own department of obstetrics at Johns Hopkins. As many of you know, twice a year one of your assistant residents braves the uncertainty of Maryland weather and the vagaries of Johns Hopkins Hospital food, to spend six weeks with us in Baltimore. In exchange, your professor of obstetrics accepts one of our assistant residents for the same period. Save for a brief interval, this semiannual interchange has gone on since May, 1927, a period of almost fourteen years. Since these men visit the other clinic only after prolonged experience in their own institutions, they are in a position to evaluate the new methods seen and the new points of view encountered with a mature critique, and can take for their own what they like and leave what seems less desirable. It is thus a broadening experience in their postgraduate education; and I believe I voice the opinion of Dr. Irving as well as my own in saying that I hope the bond between the two institutions which this interchange has established may long continue.

In the course of any undertaking it becomes desirable from time to time to take stock of present achievements and ask, Whither are we going? The present moment would seem ripe for such

an inquiry, since recent events in Europe leave no doubt that in obstetrics, as in other branches of knowledge, little can be expected from that source for many years, possibly for many decades. During the last three centuries the torch of leadership in obstetrics has been carried, in turn, by three countries in the seventeenth century by France, where the labors of Paré, Mauriceau, de la Motte, Dionis and others first made it possible for men to gain access to the delivery chamber (without being burned at the stake), in the eighteenth century by England, where Smellie, William Hunter, Charles White, Denman and others succeeded in raising the status of obstetrics from the buffoonery of male midwifery to the dignity of a profession, and, finally, in the nineteenth century by Germany, where the studies of von Brier, Naegele, Semmelweis, Michaelis, Credé and a host of others infused scholarship into obstetrics and made it one of the great branches of medical knowledge. During the first four decades of the present century, the contributions of American obstetricians have been such that even in the natural course of events, leadership would probably have fallen to us. But with the present chaos abroad, there can be no doubt where the onus lies. Yes, if advances are to be made in obstetrics during the twentieth century, it looks very much as if we must make them. This is a heavy responsibility. What are we to do about it?

By way of reassurance, let us recall that the record of American obstetrics is already one of which we may well be proud. Your own Autocrat of the Breakfast Table, almost a hundred years ago, was the first to demonstrate conclusively the contagiousness of puerperal fever, and shares with Semmelweis the glory of discovering the cause of that great scourge. At about the same period, but far removed from the Boston of Holmes, a group of pioneers on the very outposts of American civilization were making another important contribution to obstetrics, but one that

^{*}An address delivered at the Walter Channing Day dinner at the Boston Lying-in Hospital, October 24, 1940.
From the Department of Obstetrics, Johns Hopkins University and Hospital.

†Professor of Obstetrics, Johns Hopkins University School of Medicine and Obstetrics-in-Chief, Johns Hopkins Hospital.

is less well known. This almost forgotten contribution of frontier America to obstetrics would seem to merit a few minutes' consideration.

As you all realize, throughout the greater part of the nineteenth century cesarean section was the most fatal of surgical procedures, the mortality in Great Britain and France, for instance, approximating 85 per cent prior to 1865; in Paris, during the ninety years ending in 1876, not a single successful cesarean section had been performed. In the face of such results, it is not surprising that many obstetricians of the nineteenth century doubted the wisdom of ever resorting to this procedure, and predicted that the operation would shortly lapse into desuetude. The turning point in the evolution of cesarean section was the appearance in 1882 of a monograph by Max Sänger, then a twenty-eight-year-old assistant of Credé in the university clinic at Leipzig, in which he recommended the routine employment of carefully placed uterine sutures. Prior to this time, both in England and in Europe, uterine sutures were regarded not only as unnecessary but as actually harmful, since they seemed to predispose to suppuration. Sänger's recommendation, therefore, was completely at variance with the views then prevalent and, curiously enough, was based on his experience with but one case. Nevertheless, his contentions were supported by such carefully documented evidence, and his facts marshaled in such a logical and convincing manner, that the justice of his claim was apparent. Confirmation of his convictions followed quickly. Within a few years uterine suture was recognized as an indispensable part of cesarean section, and forthwith the modern operation came into being. Recalling, now, that Sänger's recommendation was founded on a single experience only, the question naturally arises, Whence came his idea? What were the sources of that carefully documented evidence in favor of the uterine suture? Who were his forerunners?

The answer to this question Sänger, himself, states frankly and without reserve. His predecessors were certainly not his colleagues in the sophisticated centers of Europe who, as we have said, opposed the suture, but were—oddly enough—certain pioneer surgeons working in the outposts of the American frontier. From Toledo to New Orleans these men had reported seventeen cases of cesarean section in which silver-wire sutures had been placed in the uterus, with the lowest mortality ever recorded. These cases are all carefully tabulated in Sänger's monograph, and full credit is given the Americans for having been the first to demonstrate the value of uterine suture in cesarean section. In all fairness to Sänger, it

must be stated that it was his study that dealt the final blow to the old methods. He not only advocated the routine use of aseptic sutures, but showed in the minutest detail how to insert them; and by combining the scientific principles of wound coaptation with full Listerian technic, he created at one full stroke the modern operation. But to have furnished the supporting data for Sänger's hypothesis and to have devised and demonstrated the earliest successful type of uterine suture were certainly no mean achievements, and they may be recalled with pride as contributions of frontier America to cesarean section.

Some years ago, we had as a visitor to our clinic Dr. Ernst Philipp, now professor of obstetrics and gynecology at the University of Kiel. After he had spent a year in this country and had visited our leading clinics, I asked him how obstetrics here differed most markedly from obstetrics in Germany. His answer was immediate: obstetrics in the United States, he said, is far ahead of that in Germany in two respects: prenatal care, and anesthesia and analgesia. Myself a graduate of Yale and a member of the faculty of Johns Hopkins, I state with mixed feelings the fact that both these movements received their greatest impetus at Harvard. Since many of you are far better acquainted than I am with the early work in these two fields, I shall simply mention most briefly the fact that prenatal care, as we understand it, may be said to date from 1901, when the Instructive Nursing Association of this city began to pay prenatal visits to some of the women in the Outpatient Department of the Boston Lying-in Hospital. So far as anesthesia and analgesia are concerned, the very word "anesthesia," of course, was proposed by Holmes. Here in Boston, also, Dr. N. C. Keep on April 7, 1847, was the first American to administer ether to a patient in labor. A month later, Dr. Walter Channing, to whose memory we pay homage now, administered ether before applying forceps; his monograph on the subject, the first comprehensive survey of the relief of pain in labor, appeared the following year. Entitled *A Treatise upon Etherization in Childbirth*, it analyzes the results in five hundred and eighty-one cases, eighty-seven his own and the remainder derived from other sources in the country. And today, it is gratifying to know that this old tradition is being continued here and that, amid the huge modern literature on the subject, the one article that is a standard for all others comes from this clinic, under the authorship of Irving, Berman and Nelson.

But enough of the past. What of the present and future? One of the most conspicuous of re-

cent trends has been the tendency to combine obstetrics and gynecology as a unified specialty. A favorite topic for presidential addresses,—and indeed for occasions of just this kind,—numerous dissertations have been delivered on this subject; without exception, so far as I know, they all urge the combination with a fervor reminiscent of the Crusades. In Europe, as well as throughout the British Empire, obstetrics and gynecology have long been regarded as a single specialty, and there this union appears to function satisfactorily, both in practice and in university work. Obstetrics and gynecology are concerned with a single group of organs, the female reproductive tract. It is becoming increasingly evident, moreover, that many of the changes which the maternal organism undergoes in pregnancy are simply exaggerations of certain alterations that the nonpregnant woman exhibits every month; that the same hormones which control pregnancy and labor govern also many phenomena in the nonpregnant woman, including menstruation; and that abnormalities in the hormone balance are probably responsible for some of the major disturbances of pregnancy as well as for those of menstruation. Indeed, recent research in endocrinology has so welded obstetrics and gynecology that any basic study in either subject is becoming almost impossible without an intimate knowledge of the other. And so far as clinical work is concerned, it is widely recognized that no one can practice either specialty with full competence unless he has some knowledge of the other.

In consideration of all these valid reasons for a combined department, I venture to cite another point of view—my own point of view—with some diffidence. I can do so most succinctly, if it is not beneath the decorum of this occasion, by recalling the refrain of an old musical comedy song, which runs, "You Can't Play Every Instrument in the Band." During the six years I spent in a combined department, I remember going, on occasion, from the operating room, where prolapse of the uterus may have been the problem at hand, to the nursery for the newborn where perhaps a case of atelectasis was under survey; from there to the carcinoma clinic, where the cytologic structure of a cervical growth may have been under discussion, followed by an argument with the physicist as to the best type of roentgen-ray therapy for a pelvic carcinoma; from there to the prenatal clinic or ward, where possibly a case of pre-eclampsia or some medical complication of pregnancy was proving worrisome; and thence to the delivery room, where a woman with a borderline pelvis was being given a test of labor. Now,

there may well be men who are capable of knowing intimately these several fields, who can keep up with the literature in each and whose clinical and operative skill in each is exemplary. There may be; but I myself cannot claim such versatility, and I am certain that the average man cannot attain excellence in so many disciplines; and, after all, we must tolerate no compromise with excellence. It seems to me beyond question that every man who proposes to engage in either obstetrics or gynecology must have sound fundamental training in the other field, including major operative work, but as he leaves his house-staff period, it is my belief that his interests and capabilities, as well as fortuitous circumstances, will naturally—and for the good of all concerned—narrow the major part of his work to one field or the other. Indeed, is not the basis of all modern specialization the fact that to attain excellence in a given field it is necessary to limit the scope of that field? Witness the fields of brain surgery, thoracic surgery and rectal surgery. If we are to attain excellence in obstetrics, if we are to make advances in it, it seems to me that we shall be most likely to do so if our efforts are concentrated on the problems of that specialty rather than disseminated over the manifold aspects of obstetrics and gynecology.

Students of jurisprudence claim that the best laws are those which repeal earlier laws—which correct previous errors of legislation. Obstetrics, too, has its laws, or at least traditions so old and deeply entrenched that they assume all the inviolable character of laws. Most of these are good and must be clung to. But our modern canon of obstetrics, let us recall, is built on foundations laid in times very different from ours—when the facilities of the modern hospital were undreamed of, when abdominal surgery was a desperate undertaking and when blood transfusion was unknown. Half a century ago, furthermore, the tools and methods of investigation were crude in contrast to ours, and some of the theories that had their genesis in that epoch are possibly open to question. For these and other reasons, certain of these old teachings have tended, I fear, to deter rather than promote obstetric progress. May I cite three examples of what I mean?

Until recent years, one of the most deep-rooted obstetric teachings had to do with the belief that the bag of waters played the principal role in cervical dilatation and was therefore indispensable to normal labor. It was for this reason that artificial puncture of the membranes, a favorite method of inducing labor in the eighteenth century, was abandoned early in the nineteenth century in favor of bags and bougies. Emphasized in

textbook after textbook, this conception that the hydrostatic action of the amniotic sac is essential for normal labor has long been regarded as an almost axiomatic truth. It has been part and parcel of all our obstetric teaching, and until very recently we have found it difficult, as did obstetricians a hundred years ago, to view without prejudice the deliberate puncture of the membranes for the induction of labor or any other purpose. It was not until some ten years ago that a group of American obstetricians had the openness of mind and the fortitude to challenge this old doctrine by rupturing the membranes to induce labor. We now know, on the basis of thousands of cases, that this is usually the best method of initiating labor and that the bag of waters has little or no function in cervical dilatation and effacement. In other words, this old and fallacious doctrine served, for a century and a quarter, to discredit and hold in desuetude one of the most valuable obstetric procedures.

My second example is of quite a different nature, and concerns itself with the age-old belief that interference with the childbearing career of a woman is at variance with the highest medical ethics—a blot on one's obstetric conscience. In an analysis of over forty-five thousand consecutive deliveries, we have found that women who have borne eight or more children experience three times the maternal mortality in subsequent pregnancies, and twice the stillbirth mortality met by women in the lower parity brackets. Study of the causes of death in these grand multiparas shows that they are usually a well-defined group of conditions, which, in turn, are basically brought about by reproductive senility. In view of the great hazards faced by these women in childbearing and the transcendent value they have to their large families, we are recommending sterilization in all women who have had eight or more children, solely on the grounds of great multiparity. This is usually done under local anesthesia, early in the puerperium. Although this practice may offend the sensibilities of some obstetricians, we regard it as a prophylactic step in reducing maternal mortality. Indeed, if every woman at the time of conception could be a healthy woman, our maternal mortality, I am certain, would be reduced forthwith by one quarter.

My third and last example has to do with the use of pituitary extract in labor. Because untrained or injudicious practitioners have used the drug in excessive doses, or in obstructed labors, many tragic accidents have resulted; and consequently it is widely held that this substance should never be used before the baby is born. Despite

the fact that uterine inertia is the commonest cause of dystocia and not infrequently ends in intra-partum infection, Dührssen's incisions and difficult mid-forceps operations, I long held to the orthodox viewpoint, objecting to the employment of pituitary extract during the first and second stages, particularly by the intramuscular route. A few years ago, one of our assistant residents returned from his service at the Boston Lying-in Hospital very enthusiastic about the therapy used here in inertia, namely, minute doses of intramuscular pituitary extract in association with analgesia. I was frankly skeptical, but permitted a trial, with the reservations that the initial dose should never exceed 1 minim, that the maximal single dose should be 2 minims and that the utmost care should be used in avoiding its administration in obstructed labor. We have now employed this program in uterine inertia for two years and have reduced our incidence of difficult mid-forceps operations from ten or twelve a year to one or two; the need for Dührssen's incisions has diminished proportionately; and there have been no untoward results. Here, then, is another break with an old tenet, which, in cautious hands, seems advantageous.

In citing these three examples of outmoded theory and practice, I have no desire to discredit the great mass of obstetric knowledge handed down to us, but wish merely to recall that obstetrics is still trammled by some ideas that are not valid, the legacy of a day long past. If obstetrics is to keep pace with modern knowledge, we must be constantly scrutinizing, with an open mind and wary alacrity, the old teachings as well as the new.

Having mentioned, in rapid succession, artificial rupture of the membranes, the sterilization of grand multiparas, the use of pituitary extract in labor, and analgesia, my conscience gives me pause, for I can see at once a host of obstetric worthies rising in opposition, with the accusation that a prophet of unbridled radicalism is before you. I can hear the old objection that labor is a normal process in which we should brook no interference, unless it is urgently needed. I can hear, in particular, the objection that such artificial procedures, if employed by practitioners of obstetrics throughout the country, are bound to result in countless disasters. In regard to the first objection, namely, that we should not interfere with such a natural process as labor, this accusation has been brought against almost every advance that has ever been made in obstetrics. I have no doubt that emphasis on this principle has done much good, for it has militated against injudicious interference, but if we are to answer truth-

fully the question, "Whither American obstetrics?" we can only acknowledge that obstetrics, in the hands of specialists at least, is veering in the direction of substituting, at various stages of labor, artifice for the oft-times slow, ineffectual and cruel vagaries of Nature. In the last quarter of a century the incidence of cesarean section in the lying-in hospitals of this country has increased fivefold, the frequency of elective low-forceps operations has shown an even steeper rise, whereas analgesia to the point of amnesia is almost routine in most large centers. It is true that some of these practices are at times used ill-advisedly, but if anyone's nostalgia for the "old days" persuades him that we shall ever go back to the "natural obstetrics" of a few decades ago, he is grievously in error. And he is in error because our obstetrics today is better obstetrics than that practiced by our fathers, as shown by the only valid criterion, namely, end results in thousands of cases. Fewer mothers die, fewer babies die and fewer women are left scarred, either physically or mentally, as the result of the process.

The type of obstetrics to which I refer, of course, is that practiced by the modern obstetric specialist—the man who has had long years of training in operative obstetrics and has an even keener eye for contraindications than for indications. He can almost sense when artificial rupture of the membranes would be hazardous or when elective forceps might lead to difficulty. What will be the outcome if the rank and file of general practitioners, who read about these procedures and observe them in clinics, attempt to practice them? I can give you some idea of what I think would happen by saying that among the cases referred to the Johns Hopkins Hospital after unsuccessful attempts with forceps by outside physicians, the majority show on admission a cervix that is less than eight centimeters dilated. Since the majority of babies in the United States are delivered by general practitioners, this problem is difficult to meet, but of one thing I am sure: our standards of obstetrics in maternity hospitals cannot be dictated by the capabilities of the general practitioners. I am equally certain that the average general practitioner, the man who is devoting but a fraction of his time to obstetrics, will do far more harm than good by indulging in the artifices which the specialist is using. Just because a man can do a spinal puncture is no indication that he can do a laminectomy; and the general practitioner must

understand his limitations and the fact that only in expert hands and in a well-equipped maternity ward can Art improve upon Nature, and then only when seasoned judgment is used. I realize full well the implication of what I am saying, namely, that two types of obstetric practice are likely to be evolved, one followed by the specialist and the other by the general practitioner. Illogical as it may appear, I can see no other solution; and perhaps, in the long run, such an arrangement might prove advantageous. Under such circumstances, the general practitioner might regard obstetric surgery in the same light that he views other types of major surgery, and realize more fully than he does now the need for consultation in the major complications of pregnancy and labor.

Having stressed the fact that many of our obstetric teachings are derived from a time far removed from ours, I should like, in concluding, to point out that many of our ethical concepts originate from an even more distant period, when the social, economic and religious circumstances of life were altogether different from what they are today. It may well be that these old ethical teachings in regard to contraception, sterilization and abortion constitute our salvation, but in a changing social order it behooves us to examine each with unbiased perspective, to be sure that it makes for the greatest good of the greatest number. As an example of what I refer to, the psychiatrists are continually coming to us with their scourging genealogical histories,—their records of unfit giving birth to still more unfit,—and they beg for sterilization, even for abortion. I should not venture to answer this difficult and far-reaching question, but bespeak merely an attitude of mind unshackled by rules that were helpful a century ago.

There are other trends to which I might refer. But I have said enough, I believe, to make plain my viewpoint. Progress in obstetrics must depend on approaching its problems with an open mind, a mind willing to evaluate today's questions in terms of today's knowledge. If we do but this, I venture to hope that some future historian of obstetrics, as yet unborn, will write:

In the twentieth century the torch of leadership in obstetrics was carried by the obstetricians of the United States of America; they found obstetrics still fettered by traditions that were as outworn medically as they were sociologically; they left it a liberal, progressive science, sensitive at once to the best interests of the patient and the needs of a changing civilization.

THE EDUCATION OF THE INTERN*

NATHAN SMITH, M.D.†

Introductory Remarks by

NATHAN B. VAN ETTEN, M.D.‡

NEW YORK CITY

I AM going to introduce briefly a gentleman who will tell you what we are doing at the Morrisania City Hospital for the training and education of interns. In presenting this study of intern education, we are making a record of obedience to the requirements of the Council on Medical Education and Hospitals and of the American College of Surgeons.

The Morrisania City Hospital is one of the twenty-six municipal hospitals in New York City. Its normal bed capacity of 539 is frequently exceeded, and with an average patient's stay of nine days, a large clinical procession is reviewed by the interns and residents. The student body is composed of fourteen residents and thirty-four interns, a ratio of intern to patient of 1:15.

To qualify for endorsement, an effort has been made to carry out in detail not only the letter but the spirit of the Council's requirements, and to go farther into the field of educating interns in the practicalities of medical care, to prepare them for similar problems that may later arise in their private work.

Medical education is far from a finished product, partly because it attempts to do too much through the long years devoted to it. In spite of the eight college years required for the degree of doctor of medicine, so much time that should be spent in teaching practical clinical treatment is devoted to smatterings of specialties that the students are in a confused state of mind when they receive their degrees. At the Morrisania City Hospital, we are impressed with the fact that the new interns have very little practical understanding of the meaning of a medical career. The Council undoubtedly desires to raise the quality of medical education. It will be making a real accomplishment if it can raise the level of the medical intelligence of the average doctor, so as to fit him for the better care of the average patient.

The general practitioner must not be frightened out of confidence in his ability to take care of the usual surgical, obstetric and medical problems. He is one of the most valuable citizens in this republic, and must be given the right kind of educa-

tion. The force of opinion may demand a better practical education for the general practitioner, so that he may be able to render better medical service to people on low incomes.

The Council would probably do well to resurvey all medical schools to discover any failures to solve this problem. It has the equipment, the personnel and the funds to do this work, and I believe that it should be encouraged to undertake it.

Ten years ago, a young man, Dr. Nathan Smith, entered the administrative service of our hospital, and so quickly showed an unusual interest in intern training that the executive direction of it was assigned to him. Although every encouragement was given to inquiring minds, the greatest emphasis was placed on the practical application of medical knowledge. In 1936, Dr. Smith developed a scheme for intensive training in the Outpatient Department, where the interns could closely observe ambulatory patients such as they might meet in their own offices. This has proved to be a successful adventure into reality.

Dr. Smith also arranges for lectures on practical subjects on forty Wednesday afternoons during each year. The subjects are chosen by the interns, and the lectures are given by distinguished New York physicians.

He will now give a general outline of his plan for the education of interns.

* * *

Recent years have been marked by outstanding advances in the field of intern education. The comprehensive study of hospital internships initiated by the New York Committee on the Study of Hospital Internships and Residencies under the guidance of Dr. Jean Alonzo Curran, executive secretary of the committee and now dean of Long Island Medical College, has served as a stimulus to many hospitals for a better organization and conduct of intern education.

The internship has become a very essential part of the clinical preparation of the student in medicine. It is now widely realized that it provides a most desirable contact and experience with the problems and responsibilities of clinical work and helps to bridge, in a satisfactory manner, the transition from academic life to that of the practitioner.

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 15, 1940.

†Deputy medical superintendent, Morrisania City Hospital.

‡President, American Medical Association.

Because nearly all graduates in medicine are taking internships, and are often devoting not only one but several years of their lives to this form of practical training, it is most essential that the internship offered and accepted be properly organized to provide the incumbents with the type of training and experience that will best supplement their previous instruction.

The acceptance of interns implies a definite obligation on the part of both the intern and the hospital and its staff. The former is under definite obligation to give faithful, conscientious service, to fulfill scrupulously his contract and to follow the hospital rules and regulations.¹ The hospital that has interns must also accept the responsibility that this implies. The intern is there to complete with practical work and suggestions the largely theoretical part of his earlier education. His training should lie in the hands of the hospital, just as the training in the medical school is now carried on by the faculties of our medical colleges.

When it is considered how much the graduates of our medical schools still have to learn through practical experience, and how many of them go out from our internships to become the sole medical advisers of patients, the responsibility of the hospitals for their training is an important one.

The intern's schedule should be planned in such a manner that he will derive all the benefits of a varied and instructive program. Nothing should be taken for granted. Any hospital that has an adequate supply of clinical material may very readily adopt the suggestions and material used in this presentation.

PLANNING THE INTERN SCHEDULE?

The student just out of medical school comes to a hospital for the chief purpose of acquiring knowledge. The establishment of a schedule before the intern group comes in and the carrying out of that schedule are dependent on careful planning in preparing for future work in general practice. These functions in some institutions are highly administrative procedures. However, the administrator should take into consideration the advice and counsel of his medical board.

The value of the internship necessarily varies with the quality of the hospital in which it is spent. Generally speaking, students with better training apply to and are absorbed by the better hospitals. Thus it happens that a poorly trained graduate may be further damaged by an internship served in a poorly organized and poorly conducted hospital.

The hospital that accepts interns should act as

in educational department that undertakes to give them training calculated to meet the needs of their future potential patients, as well as for the immediate requirements of the patients in the hospital. The institution must realize that the medical school cannot be expected to produce fully trained doctors; it can at most hope to equip students with a limited amount of fundamental knowledge, to train them in the method and spirit of scientific medicine, and to launch them with a momentum that will make them active learners, observers, readers, thinkers and experimenters for years to come. In short, the hospital should be the finishing school of the young doctor who has just graduated from medical school.

It is obvious that for the study of disease and the training of interns there must be an adequate supply of clinical material. Diagnosis, treatment and teaching should be the function of an able staff. A systematized schedule containing medicine, surgery, pediatrics, obstetrics and related specialties is essential, and the schedule must guarantee the training of the practical doctor without gaps. A general hospital with all the branches of medicine and surgery should assure the intern of the opportunity to learn all types of disease.

PERIOD AND TYPE OF INTERNSHIP

Different opinions are held as to the length and type of training for an intern before commencing practice. An internship for the general practice of medicine should last for at least two years and the service should be a rotating mixed one. Regardless of whether the young intern is aiming for general practice or a special residency, the general duties and training should be identical. In the rotating mixed internship special arrangements should be made for the person who intends to specialize in surgery by having him devote more time to it, but at no time should he be deprived of the essentials in medicine.

Table 1 gives a schedule that is the result of a careful study and many revisions; it demonstrates the two year rotating mixed internship very well. This may be of interest for the purpose of comparison with other schedules.

The total number of months spent on each service, on both the medical and surgical appointments, is as follows:

SURGICAL APPOINTMENT

Surgery, 10½ months

Three months as "junior" on general surgery with pathology, covering his own clinical and surgical pathology and including instruction in anesthesia.

Three months as assistant senior on skeletal surgery, including traumatic and orthopedic surgery.

One and a half months as "senior" on general surgery, including gynecology.

Three months as "house" on general surgery.

Medicine, 4½ months.

Three months as "junior" with pathology, covering his own clinical pathology.

One and a half months as "senior."

Obstetrics, 6 weeks.

Pediatrics, 6 weeks (covering his own clinical pathology).

Eye, ear, nose and throat and Chest Service, 6 weeks.

Outpatient Department, 6 weeks (special clinic schedule).

One and a half months as "senior" on general surgery, including gynecology.

Obstetrics, 6 weeks.

Pediatrics, 6 weeks (covering his own pathology).

Eye, ear, nose and throat and Chest Service, 6 weeks.

Outpatient Department, 6 weeks (special clinic schedule).

Ambulance and emergency-room service, 3 months.

This, however, means only forty-five days of actual riding, since the interns work on alternate days only. It also includes active participation in the treatment of acute emergency patients who either walk in or are transported to the emergency room.

TABLE 1. *A Model Intern Schedule for a Two-Year Rotating-Mixed Service.**

PERIOD	ASSIGNMENT	INTERN A	INTERN B	INTERN C	INTERN D
First three months	Junior	Surg. I and path. intern	Surg. II and path. intern	Med. I and path. intern	Med. II and path. intern
Second three months	Junior	Med. I and path. intern	Med. II and path. intern	Surg. I and path. intern	Surg. II and path. intern
Third three months	Pediatrics and Obstetrics	Ped., 6 wk. Obs., 6 wk.	Ped., 6 wk. Obs., 6 wk.	Obs., 6 wk. Ped., 6 wk.	Obs., 6 wk. Ped., 6 wk.
Fourth three months	Ambulance	Amb.	Amb.	Amb.	Amb.
Fifth three months	E. E. N. T. and Chest Service, and Specialty Clinic	Spec. Cl., 6 wk. E. E. N. T. and C. S., 6 wk.	Spec. Cl., 6 wk. E. E. N. T. and C. S., 6 wk.	E. E. N. T. and C. S., 6 wk. Spec. Cl., 6 wk.	E. E. N. T. and C. S., 6 wk. Spec. Cl., 6 wk.
Sixth three months	Assistant senior	Skeletal surgery	Skeletal surgery	Skeletal surgery	Skeletal surgery
Seventh three months	Senior	Surg. I and Gynecol., 6 wk. Med. I, 6 wk.	Surg. II and Gynecol., 6 wk. Med. II., 6 wk.	Med. I, 6 wk. Surg. I and Gynecol., 6 wk.	Med. II., 6 wk. Surg. II and Gynecol., 6 wk.
Eighth three months	House	Surg. I	Surg. II	Med. I	Med. II
		INTERN E	INTERN F	INTERN G	INTERN H
First three months	Junior	Med. I and path. intern	Med. II and path. intern	Surg. I and path. intern	Surg. II and path. intern
Second three months	Junior	Surg. I and path. intern	Surg. II and path. intern	Med. I and path. intern	Med. II and path. intern
Third three months	Ambulance	Amb.	Amb.	Amb.	Amb.
Fourth three months	Pediatrics and Specialty Clinic	Spec. Cl., 6 wk. Ped., 6 wk.	Spec. Cl., 6 wk. Ped., 6 wk.	Ped., 6 wk. Spec. Cl., 6 wk.	Ped., 6 wk. Spec. Cl., 6 wk.
Fifth three months	Assistant senior	Skeletal surgery	Skeletal surgery	Skeletal surgery	Skeletal surgery
Sixth three months	Senior	Surg. I and Gynecol., 6 wk. Med. I, 6 wk.	Surg. II and Gynecol., 6 wk. Med. II., 6 wk.	Med. I, 6 wk. Surg. I and Gynecol., 6 wk.	Med. II., 6 wk. Surg. II and Gynecol., 6 wk.
Seventh three months	House	Surg. I	Surg. II	Med. I	Med. II
Eighth three months	Obstetrics, and E. E. N. T. and Chest Service	E. E. N. T. and C. S., 6 wk. Obs., 6 wk.	E. E. N. T. and C. S., 6 wk. Obs., 6 wk.	Obs., 6 wk. E. E. N. T. and C. S., 6 wk.	Obs., 6 wk. E. E. N. T. and C. S., 6 wk.

*This schedule has been in operation in a hospital of approximately 540 beds but lends itself very readily to a smaller hospital. By dividing the schedule in half it may be used for a hospital of 250 or 300 beds.

Ambulance and emergency-room service, 3 months.

This, however, means only forty-five days of actual riding, since the interns work on alternate days only. It also includes active participation in the treatment of acute emergency patients who either walk in or are transported to the emergency room.

MEDICAL APPOINTMENT

Medicine, 7½ months.

Three months as "junior" with pathology, covering his own clinical pathology.

One and a half months as "senior."

Three months as house.

Surgery, 7½ months.

Three months as "junior" with pathology, covering his own clinical and surgical pathology.

Three months as "assistant senior" on skeletal surgery, including traumatic and orthopedic surgery.

As will be seen in the above schedule, the only differences are that the surgical intern receives three more months of surgery than the medical, and the medical intern three more months of medicine than the surgical. Although this program has been devised for and has been in operation in a public hospital, it is sufficiently flexible to be used in any general hospital.²

It has always seemed to me that the training in the office specialties has been grossly neglected. Very few interns have any experience in the practical problems of home and office practice. It is a foregone conclusion that a small number are likely to become specialists, but all are confronted at first with general office practice. Therefore, the six-weeks outpatient specialty service is included at

the beginning of the second year of the internship.

The intern is assigned to these clinics as part of his regular rotating service. A systematic program of instruction in the form of postgraduate training is conducted by the senior members of the visiting staff, and includes the following specialties: venereal disease, office gynecology, urologic diagnosis, dermatology, allergy, proctology, physiotherapy, electrocardiography and injection of varicose veins, the greater number of which he will encounter in his office practice.³

It is not unusual to find that an intern, after completing his two-year internship, is not able to perform a diathermy treatment, treat a case of hay fever, treat an uncomplicated case of gonorrhea or read an electrocardiographic tracing. The average intern may attempt these without realizing their limitations; others have to resort to the

and the proper attitude toward the nursing staff, the attending staff and other members of the hospital organization.

After the preliminary personal interview the interns are introduced to the members of the medical board, the members of their medical staffs and the heads of divisions of the hospital, and are taken on a tour of inspection through the institution.

Two days previous to commencement of their internship the new members of the house staff are given a complete physical examination, including x-ray examination of the chest, a complete blood count, urinalysis and other laboratory data that may be indicated. These examinations are repeated annually, and an effort is made to correct any abnormalities.

In the Morrisania City Hospital, through the co-operation of the administrative, attending, res-

TABLE 2. *Schedule of Specialty Clinics and Periods of Instruction.*

MONDAY	TUESDAY	WEDNESDAY	THURSDAY	FRIDAY	SATURDAY
9 00-10 00 X-Ray	9 00-9 45 X-Ray and Fluoroscopy	9 00-9 45 X-Ray	9 00-10 30 Physical therapy	9 00-11 00 Lecture	9 00-10 30 X-Ray and Fluoroscopy
10 00-11 00 Baby Health	9 45-10 30 Genito-urinary	9 45-10 15 Basal metabolism	10 30-12 00 Gonorrhea	11 00-12 00 Tumor	10 30-12 00 Endocrine

1 30-2 30 Gynecology	2 30-5 00 Rectal	2 00-3 00 General conference	2 00-3 00 Peripheral Vascular	2 00-5 00 Allergy	
2 30-5 00 Peripheral Vascular		3 00-4 00 Skin	3 00-5 00 Diabetes		
		4 00-5 00 Instruction in x-ray technique			

various circulars issued by drug houses relating to treatment of these specialties, and still others obtain information from the salesmen who sell the various types of apparatus.

Table 2 gives the schedule of specialty clinics used in the Morrisania City Hospital.

INTRODUCTORY PROGRAM FOR THE NEW INTERNS

In dealing with problems of hospital administration the administrator sometimes overlooks the problems of the "new intern," who has difficulty adjusting himself to a new environment, a new hospital and a new routine.

It is therefore important that the intern, before commencing his internship, be given a personal interview by the superintendent and his assistants, at which time credentials are examined and the hospital executives discuss, emphasize and clarify the following points: the rules and regulations of the hospital, an outline of routine duties, the care of the patient, the treatment of the patient's family,

ident, nursing, social-service and dietary divisions, it has been possible to formulate a program that is applied to the members of the intern group on five consecutive days prior to commencement of their duties. The program consists of seven lectures and demonstrations at which time the intern is carefully instructed in the meaning and work of these various divisions, as outlined below:

INTERN PROGRAM

Lecture 1.

Discussion of rules and regulations of Morrisania City Hospital: medical superintendent.

Discussion of intern schedule and hospital forms: deputy medical superintendent.

Discussion of social-service problems and activities: director of social service.

Discussion of dietetics in health and disease: chief dietitian.

Orientation tour of hospital and short discussion on nursing problems: superintendent of nurses.

Lecture 2. Practical demonstrations*

Infusion and phlebotomy
Hyperdermoclysis
Thoracentesis
Paracentesis
Pneumothorax
Lumbar puncture
Surgical dressings

Lecture 3. Practical demonstrations

Operating room technic

Preparation

Change of uniform
Cleansing hands
Sterile gown and gloves
Approach to operating field
Changing gloves during operation
Changing position during operation

Care of patient after operation

Examination for iodine
Dressings

Rules of operating room for spectators

Caps, gowns and masks
Amphitheater

Set-up of instruments and their care

Needles
Syringes
Scissors and so forth

Demonstration of surgical hemostasis and closure (surgical knots)

Restraints

Adults

Ankle and wrist
Shoulder
Body
Bed sheet
Canvas with straps
Sideboards

Children

For examination
Jacket for active child

Lifting and turning of patients in bed

Daily care

Hair
Nose
Mouth
Ears
Back

Lecture 4. Practical demonstrations

Counterirritants

Flaxseed poultice
Mustard paste
Turpentine stupe
Mustard bath for children
Croup tent

Enemast†

Purpose
Types (cleaning, oil, carminative, stimulative and so forth)
Medications and materials

Irrigations

Purpose
Types (ear, nose, throat, eye)
Supplies used

Lecture 5. Practical demonstrations

Cold sponge bath
Cold pack
Prevention and care of bed sores

Lecture 6. Practical demonstrations

Tracheotomy (done in the morgue)
Insertion of tracheotomy tube
Nasal pack

Lecture 7. Practical demonstrations

Drinker respirator and inhalator
Resuscitation apparatus
Oxygen tent
Incubator
Operation of blood bank and blood transfusion
Instructions in standard nomenclature of disease and hospital records
Ambulance requirements and management of emergencies
First-aid treatment of fractures and dislocations
Instructions in laboratory procedures
Instruction in procedure for obtaining consent for post-mortem examination and the performance of autopsies

The demonstration of a mustard paste or an ear irrigation may appear to be beneath the dignity of an intern, but as a matter of fact when these demonstrations were given the interest of the interns was manifested and led to many constructive inquiries. Although this may appear to be and is fundamental, its purpose is to familiarize the new intern with the essentials of common procedures too frequently either overlooked or entirely forgotten. They are procedures a doctor in practice may be called upon to perform or direct.⁴

The five days in the hospital prior to the commencement of internship may be called the "critical period," because it is during this time that the intern is familiarized with the established standards of the hospital. This period of introduction to the hospital has created a unity of spirit and a better co-operation between the attending staff, interns, nurses, employees and administrators, and this has provided better care for the patient.

It has been my experience from careful observation that once an intern has been started properly in his work, he will continue to give universally acceptable service; on the other hand, should he get into bad habits during his first week he will probably retain them during his entire internship.

The details of each of the above-mentioned lectures and demonstrations, as well as an outline of duties, responsibilities, rules, regulations and other miscellaneous details relating to the hospital and medical practice, have been compiled in book

*The above procedures are done by senior interns, assisted by a nurse, on actual ward work.

†X-ray films are employed to demonstrate proper and improper techniques.

form. This manual is a compilation of about one hundred and forty mimeographed pages and may be referred to as the "Hospital Bible," since it covers everything. A copy of this book is given to each of the new interns for future reference.

PROGRAM OF INSTRUCTION AND EDUCATION

Wards

On the wards the intern service should be a rotating one, and no attempt should be made to turn the intern out qualified either as an internist or surgeon, although he may assist at operations and do an ordinary uncomplicated surgical case.

Ward Rounds and Bedside Teaching

Bedside work and routine ward rounds with his chief and associates should be the highlights in the day's work. Here the main concern should be differential diagnosis and treatment and the intern should be made to familiarize himself with the ophthalmoscope, auroscope and such other diagnostic apparatus and measures as are ordinarily used by the general practitioner. At this time the chief of service should review the record and make such comments and corrections on the charts as are necessary.

Laboratory Work

In the laboratories the intern should not be regarded as an employee and burdened with the time-consuming repetitious work better done by paid technicians; rather he should be expected to follow up the blood, urines and pathologic specimens of the cases to which he is assigned.

Lectures

A definite course of lectures on various subjects is highly important and definitely welcomed by the intern group. Practical lectures are given on forty Wednesday afternoons during the year on the common necessary things a doctor should know. These are given by members of the attending staff and prominent men in medicine in New York and other cities. The topics are chosen by the interns, and a partial list follows:

- Interpretation of the fundus of the eye in relation to general medicine
- Present status in the treatment of cancer
- The relation of neurology to medicine
- Treatment of common diseases of the biliary tract
- Treatment of common ear, nose and throat conditions
- The relation of public health to the practice of medicine
- Office treatment of urologic conditions
- Medical ethics
- The relation of psychiatry to medicine
- Some practical aspects of allergy
- Discussion of fundamental principles in the treatment of fractures

- Chronic arthritis
- Prenatal and postnatal care; home deliveries
- Cultural aspects of medicine
- Medical jurisprudence
- Early diagnosis of brain tumor
- Physical agents in the treatment of disease
- Low-back pain
- Treatment of heart failure
- The roentgen appearance of the normal lung and its variations
- Treatment of hand infections
- Practical prescription writing
- Therapeutics and menstrual dysfunctions
- Diagnosis and treatment of commonest skin conditions
- Practical points in pediatric practice
- Infant feeding
- Communicable diseases of the central nervous system and their public-health aspects
- Orthopedic appliances: indications and use
- Surgical emergencies
- Diseases of the oral cavity of interest to the physician
- Medical emergencies
- Modern methods of diagnosis and treatment of the common arterial diseases
- Anesthesia (surgical, obstetric and office)
- Blind diseases
- Allergic dermatoses
- Acute infections of the urinary tract
- Head injuries
- Facilities the board of health offers to the practicing physician and his obligations to the board of health
- Treatment and management of rheumatic heart disease in children
- Complications of diabetes: treatment

Departmental Conferences

The departments of pediatrics, obstetrics and gynecology, medicine, surgery, pathology and x-ray have their weekly and monthly conferences and regular rounds, at which the intern receives instruction. Interns and residents present reviews of histories, diagnosis and treatment, and these are further discussed by the attending staff.

Every casualty is minutely studied to detect an error in either judgment or procedure.

Weekly Clinical Conferences for Interns

The Educational Committee of the House Staff arranges weekly conferences for interns, consisting in the presentation of interesting cases throughout the institution. An attempt is made to correlate the clinical, roentgenologic and pathologic findings. The presentations afford a kind of forum for our young and ambitious interns in preparation for future academic endeavor and expression.

Current Literature

Interns and residents meet once a week in the hospital library and review the current medical literature. In this way the intern is given an opportunity to speak before his colleagues, to think quickly while on his feet and to address groups

of people. Therefore, he not only acts in the capacity of pupil all the time but as teacher on occasions.

The library has a full-time librarian and contains the most recent books as well as outstanding foreign and domestic journals. No hospital should be without a workable medical reference library.

Responsibilities of the Attending Staff

The intern should be given an opportunity to attend lectures, conferences and follow-up clinics, which are held in the various divisions of the hospital. During these activities the members of the attending staff should function as members of a teaching staff and should be charged with the responsibility of developing and continuing the training of the interns.

Medical Ethics, Local Laws and General Behavior

Another essential of the intern's training is to impress on him those intangible qualities that, although not often spoken of, are nevertheless of great importance. To teach him the relation between himself and the other employees, no matter how humble their station, the confidential nature of all the information he gains about a patient's condition, his proper status with relation to physicians in private practice, local laws pertaining to contagious diseases and medical examiners' cases, the question of gratuities and other ethical problems, are all matters of great importance.

Recreation

The recreational side of the intern's life is frequently overlooked, yet in view of the exacting demands made on him this should be considered an essential provision. The intern's quarters should be sufficiently isolated so that he may feel free to relax. A radio, card table, piano and, if space permits, a billiard table should be provided. For outdoor recreation a tennis or handball court—or both—is beneficial. A quiet corridor and an individual room, affording privacy, are factors for consideration.⁵

SUMMARY

Under the plan that I have outlined the intern has been trained in taking good histories and making thorough physical examinations, and has developed the art of medical logic in drawing conclusions. He has had basic training in the use of the fluoroscope, diathermy, basal metabolism and electrocardiographic equipment, and has been instructed in the interpretation of x-ray films, fluoroscopic examination and electrocardiographic readings. He has received instruction in the treat-

ment of hay fever, injection of varicose veins, treatment of common skin conditions, office gynecology, proctology and the care of the diabetic patient. He has also been instructed in medicine, surgery, obstetrics, pediatrics and related specialties.

It may be said that the form of internship recommended is a well-rounded and practical one, fostering confidence, reliability and self-assurance to assume the responsibilities of general practice. It is a source of gratification for a hospital to know that it has trained the intern adequately, and this can be done by proper study and development of a schedule similar to the one recommended.

In summary, it may be said:

There should be careful and intelligent supervision of the intern staff by the superintendent, his assistant or another executive officer, who by experience is fitted to handle the training of the intern and who is clothed with sufficient authority to effect it.

The hospital must develop practical doctors who will know what to do with the type of case they are most likely to meet.

The attending members of the staff of a hospital—although they may not be connected with an outside teaching institution—should function as teachers and should be charged with the responsibility of developing and continuing the education of interns.

All appointments to the medical and surgical staffs of a hospital should be based on merit.

The intern must be trained in doing things; if he is merely told or if he only reads, his training is inactive and hence remains on the informational basis. He will be apt to fail to acquire the practical skill or the impulse to try things needed by the general practitioner.

The Outpatient Department should play a clinical role in the education of interns. Its importance is surely sufficiently obvious; to a considerable extent the ambulant patient manifests the process of disease closer to its onset than the patient in the wards does. No small proportion of the young physician's patients will be persons who complain of aches and pains before they are forced to take to their beds.

The quality of medical service and intern teaching entails dual responsibility. It depends on interest shown both by the administration and by the medical staff.

The organization and proper utilization of the intern's time is essential in order that he may derive the necessary benefits and opportunities the hospital has to offer.

The hospital should prepare a well-organized intern program in the form of lectures and dem-

onstrations to be given to the interns at the commencement of their internship, and to cover such subjects as rules and regulations of the hospital, social service, diets and practical demonstrations of medical procedures, nursing procedures and surgical technics.

Systematic practical lectures, didactic and expository in character should present to the intern comprehensive surveys of medicine, surgery and other clinical branches.

The various medical, surgical and specialty divisions in the hospitals should make regular rounds and should hold weekly and monthly

conferences, in which the interns should be encouraged to participate.

THE USE OF SILK IN INFECTED WOUNDS*

ELLIOTT C. CUTLER, M.D.,† AND JOHN E. DUNPHY, M.D.‡

BOSTON

WE PRESENT this paper on the use of silk in infected wounds as a contribution to surgical technic. The title may well provoke immediate criticism, since even the ardent advocates of "silk" surgery have condemned its use under these conditions. But as the years have passed, one of us (E. C. C.) has given up entirely the use of catgut, because even under the condition of infection, healing has been better with silk, and hernia and evisceration have been lessened.

The advantages of using fine silk instead of catgut for sutures and ligatures in clean wounds have been demonstrated conclusively by many investigators.¹⁻⁶ Fine silk is cheaper. It is more easily and reliably sterilized. It produces less reaction in the tissues, and it results in a stronger wound. Its use imposes on the operator a more exacting technic, which is invariably followed by fewer wound complications. When silk sutures are used, wounds are less painful, and the period of hospitalization is often shortened. Investigations from this clinic in the fields of hernia⁵ and thyroid⁴ surgery have clearly supported this point of view. Infection, wound reaction and recurrence of the hernia have been lessened in our clinic by its use. The sole disadvantage of silk is that it is nonabsorbable and hence may act as a foreign body. For this reason its use in infected wounds is not generally advocated, and many surgeons hesitate to use it in clean wounds because occasionally slight long-continued suppuration and a draining sinus may develop.

Although it is true that silk is nonabsorbable in the sense that catgut is absorbed, under certain circumstances it may be completely removed from the tissues without being extruded from the wound. This is accomplished by fragmentation of the silk fibers and by inclusion of the fragments within mononuclear phagocytes. That silk may be absorbed in this fashion was shown years ago by Foot.⁷ The process by which this is achieved is shown in Figures 1 and 2. To promote absorption the silk should be composed of small fibers, twisted rather than braided, and either unwaxed or waxed very lightly. So-called "serum-proof" silk is not so easily fragmented and hence is more likely to act as a persistent foreign body and to be extruded from the wound in the presence of infection.

In sharp contrast to the common belief that silk should not be used in infected wounds, an opinion shared by some surgeons⁸ educated to the use of silk, is the curious acceptance by a large number of capable surgeons of the fact that in the field of alimentary-tract surgery, both gastric and intestinal, silk is the preferable suture material. Obviously all such cases are potentially, if not actually, the seat of infection. Halsted's⁹ clear demonstration of the superiority of silk in large-bowel surgery lent a major impetus to this point of view. In a later paper¹⁰ in commenting on the use of silk in infected wounds, Halsted wrote: "If fine silk were used and the infection slight, probably none of the buried threads would be extruded, nor would healing be delayed demonstrably on account of their presence." And very recently, following the publication of a book by one of us (E. C. C.¹¹), a letter came from a gynecologic colleague, who

 †Instructor in surgery, Harvard Medical School

surprised us by saying that the book was satisfactory except for the section on gynecology. Here, he said, we made the mistake of changing from silk to catgut, for in a long career he had proved to himself the great superiority of silk in all types of gynecologic procedures.¹²

an animal's abdomen. These were then contaminated with equal amounts of a well-shaken bacterial culture, and closure was performed using silk in one wound and catgut in the other. It was found that only 50 per cent of the silk wounds suppurred, whereas 100 per cent of the catgut

FIGURE 1.

This photograph shows a silk suture buried four months previously in a highly infected wound in the abdominal wall of a dog. Note the perfect healing, without extrusion of the silk.

The knowledge that under certain circumstances silk may be absorbed from the tissues, and the experience of one of us (E. C. C.) who has used silk for years in the presence of infection, led to a comparative study of the healing under controlled conditions in the laboratory of infected wounds sutured with silk and with catgut.¹³ Under sterile conditions parallel wounds were made in

wounds opened and discharged a purulent exudate. Moreover, the infection in the catgut wounds always appeared earlier and was severer. Healing occurred at about the same time in silk wounds that opened as in the corresponding catgut wounds. No persistent sinuses developed. Although some of the silk sutures were extruded from the wounds, healing occurred without delay

and without the removal or discharge of all the sutures. This was not true if heavy silk or continuous sutures were employed. Under these circumstances, all the silk often had to be removed from the wound before healing was complete.

Fortified by these laboratory investigations, but with no expectation of bringing adherents to this point of view, we present certain observations on

FIGURE 2

This photograph shows several strands of a twisted silk suture buried six months previously in a highly infected wound in the abdominal wall of a dog. Note the fragmentation of the silk fibers and the continued presence of some phagocytes which are persisting in their attempts to break up further the foreign body. This wound, though grossly infected, discharged no sutures.

the use of silk in potentially infected and grossly infected surgical conditions. In our opinion, the results with this material are superior to those previously obtained with catgut. However, before presenting the material let us state clearly that the silk used is fine black silk (No. 4 Gudebrod, which breaks at 4 pounds' tension) and that the greater the infection, the less numerous the sutures used.

The technic generally followed in our clinic is to close the peritoneum by a continuous silk su-

ture, single strand, which accurately approximates peritoneum to peritoneum. In placing this suture, meticulous care is taken to incorporate the transversalis fascia with the peritoneum. When a wound must be drained, an interrupted suture is always placed at each side of the drain so that this foreign body does not rest against the continuous suture. When the wound is grossly infected, once the peritoneum is closed, the layers are closed by interrupted Lembert sutures of fine silk. These are placed in long abdominal wounds in the fascia, not more than 6 mm. apart, and in the fatty layers in sufficient number to approximate the tissue and build up the wound by obliterating any dead space. If the wound is grossly contaminated, skin sutures are not placed, for if there is a small amount of infection and the skin is not closed over it, the wound will heal well without breaking down.

The realization that silk may be superior to catgut, even in infected wounds, has come slowly. Recognizing its advantage in alimentary tract surgery, we were led naturally to its use in both chronic and acute cholecystitis. Next came its employment in pelvic surgery, both in potentially infected cases and in gross infection with tubo-ovarian abscess. Once the success of repair was demonstrated in such cases we accepted silk as the superior suture material in all wounds, and have recently utilized it in all forms of surgery involving infection, including infected pilonidal sinus, infected hands and acute suppurative appendicitis.

The material that we are presenting includes studies in biliary tract and alimentary tract surgery, surgery of the large bowel, gynecology and suppurative appendicitis. The results obtained in these fields by the use of fine silk suture material are better than we have been able to obtain with the use of catgut. As others have repeatedly emphasized,—notably Whipple,⁶ who has been won over to the use of silk by clinical trial, although for years he had been opposed to it,—the type of surgical technic demanded by those who use fine silk may contribute to these results quite as much as the material employed. It is our hope, as Allen,¹⁴ of Australia, puts it, that the "fetish" of catgut may be somewhat dispelled by these observations.

Table 1 summarizes the material presented. It by no means covers all types of surgery in which we use silk, but demonstrates the common fields for surgical endeavor. Many surgeons use silk for biliary, gastric and large bowel surgery, and yet are appalled by the suggestion that it can be utilized in more serious infectious conditions. This is a peculiar paradox, for there is no more seri-

ous danger to a surgical wound than bowel contents, and in spite of so-called "aseptic" methods in large-bowel surgery a considerable percentage of wounds are contaminated. Sutures were discharged in 7 per cent of our cases, but the amount of wound infection and the small incidence of hernia, occurring only about colostomy openings, are favorable omens. All wounds under the heading "suppura-

in 11 per cent when we were dealing with an acute infectious condition. In the latter group, sutures were discharged for as long as six to eight months, but there were no cases of hernia or disruption, and none of the wounds were seriously involved by infection.

Table 3 refers to gastric surgery, including surgery of the duodenum. Here, at least in the cancer cases in which hydrochloric acid was absent, there was gross contamination in the wounds, yet

in no case was there the slightest trouble with the wound — infection, hernia or the discharge of silk sutures.

Table 4 deals with large-bowel surgery, in which we have not resorted to the use of so-called

ing, in the other about a Mikulicz procedure; in each of these operations the discharge of fecal contents usually, but not always, seriously contaminates the wound.

Table 5 covers the field of gynecology; here also, in a wound closed without drainage, some silk sutures were discharged. However, the usual course of the convalescence was so smooth that we

have become better satisfied with silk closure than with catgut. In this field, opening the vagina or amputating the cervix may expose the wound to infectious material.

Table 6 presents a thorough study of 55 cases of acute suppurative appendicitis, including 25 of perforated appendicitis with diffuse peritonitis, 20 of gangrenous appendicitis with purulent fluid and

local peritonitis and 10 of appendicitis with abscess formation. In all cases positive cultures of *Escherichia coli*, nonhemolytic streptococcus or enterococcus were recovered at the time of operation. In only 5 cases was drainage of the peritoneal cavity used. All the patients were operated on through a right oblique muscle-splitting incision. In 5 cases the peritoneum was closed with a continuous suture of fine silk; in the remainder it was closed with a continuous suture of catgut. In all cases the muscular and fascial planes were closed with interrupted sutures of fine silk. It is our practice to close the upper layers of the abdominal wall very loosely when gross infection is present. In 20 cases the fat and skin were left open, and the wound edges were packed lightly with gauze impregnated with vaseline, or were covered with sponges wrung out in physiologic saline solution.

In 39 patients the wound healed promptly over periods varying from twelve days to four weeks, the average being about twenty days. In no case was the use of silk responsible for prolonging the hospital stay. In 2 cases the continuous silk suture used in the peritoneum was discharged before the sixteenth postoperative day. Had this suture not been extruded, it is possible that healing might have been delayed. There were 14 cases of delayed healing. Of these, 6 healed within three months and gave no further trouble; in 2 the wound did not finally close for six months. Four other patients, although the wound healed promptly, continued to have trouble with occasional reopening of the wound and discharge of sutures; this continued in 1 case for six months, and in the other for a year.

Only 2 of the 14 patients were seriously incapacitated because of continued trouble with

the wound. One patient was operated on again, and a chronic sinus tract was excised; no silk was found. This wound had been drained at the time of operation, and it is impossible to say whether or not the silk used was responsible for the faulty healing. In the other 12 cases of delayed healing the patients appeared to suffer no great distress. Only 4 had to return for dressings after discharge from the hospital; in the others the wounds healed promptly but continued to break open with the occasional discharge of a suture. This caused no great inconvenience to the patients and in no way interfered with the strength or final cosmetic appearance of the wound. It is fair to state, therefore, that in 55 cases of acute appendicitis in which fine silk was used, only 2 patients suffered serious distress from the use of nonabsorbable sutures. The majority of the wounds healed promptly and well, in spite of gross contamination, and none of the patients developed a postoperative hernia.

Lastly, the statistical data show that in the presence of gross infection wounds heal much better with less reaction and less tendency to break down when the skin is not closed. Table 7 shows that in

TABLE 7. *Operations for Acute Suppurative Appendicitis: Comparative healing of silk wounds with and without skin-closure.*

infected wounds when the skin is closed, the percentage of delayed healing rises abruptly; whereas when no sutures are placed in the skin, there is no delay in healing. This is a technical point of some importance.

During the period of this study catgut was used throughout the wound in 18 cases of acute suppurative appendicitis. Table 8 compares the

TABLE 8. *Operations for Acute Suppurative Appendicitis: Comparative healing of infected wounds sutured with catgut and silk.*

*Only 1 of these was drained.

healing of such infected wounds sutured with catgut and with silk. Ten of the catgut wounds were in cases with perforation, 4 with abscess and 4 with gangrene and local peritonitis. Sixteen healed promptly, but the average period of healing

was slightly longer than that for the 39 silk wounds that healed promptly. In 1 catgut wound healing was delayed for three months, at the end of which time a catgut suture was removed. In another the wound healed well, but one year later a superficial abscess developed and a small knot of catgut was discharged. Of more significance is the fact that in this group of 18 patients there were three postoperative hernias and a weakened abdominal wound, with a broad scar but no definite hernia. Five cases in this group were drained, but only one of the hernias developed in a drained wound.

It is our impression that some factor other than infection plays a role in the discharge of non-absorbable sutures. We say this because of the great frequency with which grossly infected wounds heal without discharging sutures, and because of the occasional clean wound in which no suppuration develops but from which nonabsorbable sutures are sometimes repeatedly discharged. The placing of such sutures too close to the skin favors their discharge from clean wounds. The possibility that allergy to silk might play a part has been investigated, but we have found no case of sensitivity to this foreign protein in the silk sutures in a series of 6 patients whose wounds repeatedly discharged silk. In the present state of our knowledge it must be said that a few patients do not tolerate foreign bodies in the tissues, and that regardless of infection silk sutures may be discharged.

DISCUSSION

It is not our intention to advocate the widespread use of silk in infected wounds. However, this study demonstrates that silk can be used in the presence of infection without the disastrous results that are often attributed to it, and with certain advantages that merit consideration. The degree and severity of the inflammatory reaction are less when silk is used. This statement is based on laboratory evidence and on a clinical impression gathered from the present study. The degree of infection in the immediate postoperative course was less. Moreover, silk wounds are stronger. In the presence of infection catgut is often rapidly absorbed, whereas silk, despite suppuration around it, continues to hold the tissues together. This is an observation that we have made repeatedly in both the laboratory and the clinic. Consequently one may expect fewer hernias in infected wounds when silk is used. In the presence of infection, when minimizing the degree of suppurative infection and maintaining a strong

wound are of great importance, silk is preferable to catgut. Thus in an elderly patient after resection of the colon, even though contamination of the wound may seem likely, the use of silk will not only reduce the likelihood of suppuration but also ensure a stronger wound, with less danger of either evisceration or hernia. The discharge of a suture from the wound in such a patient is a small price to pay for superior healing.

CONCLUSIONS

Material is presented from the major fields of surgical endeavor in which infection is commonly to be expected and in which small silk sutures have been used. The evidence in this series agrees with that of controlled laboratory experiments in indicating that in infected wounds the use of fine silk sutures instead of catgut sutures, results in a more permanent and solid healing. The results also reveal that in some cases, even when healing has been complete, the extrusion of silk sutures may continue. The factor leading to this extrusion is not solely the amount or type of infection. In our opinion silk may be used with value in certain surgical fields when infection is present.

DISCUSSION

DR. ROBERT R. BALDRIDGE, Providence, Rhode Island: The paper by Drs. Cutler and Dunphy is certainly fascinating and daring. I am glad that they have not advocated the use of silk in infected wounds by the general surgical public, for such a recommendation by such eminent authors might well result in the return of the crochet hook to the place of prominence it once held in the surgeon's armamentarium. I do not believe that such excellent results as the authors report could be obtained except

by master technicians—master surgeons—working under the most favorable circumstances

It is a question in my mind whether such technic could be applied in a general hospital, for example, where the surgical teams change every few months. As Dr Whipple has pointed out the use of silk in clean wound surgery requires special training and I believe that its use in infected wounds could be undertaken only by such men who have had previous training and are skilled in the employment of silk in clean wounds.

Hilsted's principles of sharp-knife dissection careful hemostasis, avoidance of tension and of mass ligatures, use of the finest suture material and the avoidance of all unnecessary trauma would certainly be more necessary in an infected than in a clean wound.

At the Rhode Island Hospital we do not yet dare to use silk except on rare occasions, even in clean wounds although, as the authors have pointed out, we have no hesitation in adopting it in gastrointestinal surgery. At first glance this may appear inconsistent. The well known powers of resistance of the peritoneum, as compared with those of muscle fascia or fat however, probably explain at least in part, the freedom from complications.

A proper discussion of this paper must include the subject of wound healing in general. It should be emphasized that many factors aside from the suture material used determine whether or not a given wound will heal well. In addition to the fineness, strength and blandness of the suture material, we must consider the nature of the wound, the character and virulence of the bacteria, the skill and experience of the surgeon and the condition of the patient as well as that of the wound. The presence of dehydration, hypoproteinemias, avitaminosis, anemia, old age or chronic disease may interfere with healing in the most skillfully sutured incisions, and conversely, as we all know, most wounds heal without infection regardless of the suture material used provided the patient is in good general health and his surgeon reasonably skillful.

I should like to ask the authors if they will elaborate their meaning of the word infection as opposed to contamination. I have operated as we all have on a great many patients with peritonitis. There is infection within the peritoneal cavity, but there is not infection within the wound. When we sew up such a wound we are unquestionably repairing a contaminated wound. The cleanliness of all wounds however, is only relative and as Ives and Hirschfeld and others have shown bacterial contamination may be demonstrated in as high as 90 per cent of all so-called clean wounds. I bring up this point to emphasize that it is the degree of contamination and the virulence of the infecting organism, not the fact that they are present which we must consider. Would not The Use of Silk in Contaminated Wounds be a more exact expression of the meaning of the authors?

DR CLAUDE C KELLY, Hartford, Connecticut. I was trained in the surgical technic used in Baltimore and was told that many surgeons had abandoned the use of silk sutures in the presence of infection because they had later removed silk from wounds. Silk does not have to be braided or thick to result in extrusion and infection. I recall a case in which a piece of silk was extruded on reopening a wound a year after operation, the wound then healed at once.

I formerly used silk in the ligation of all the vessels in radical breast operations until on excising the mass in a few suspected recurrences I found within it a silk ligature and a drop of pus. There was nothing in the wound to indicate infection.

Judging from what Dr Cutler has said, I was wrongly trained in the use of silk, and it is remarkable that the results he describes were obtained. However, I believe that silk should not be used by surgeons inexperienced with it, especially in infected wounds.

One error in the employment of silk sutures is that of leaving long ends beyond the knots. Leaving some of the skin open has proved valuable in many infected wounds. Collier tells of using wire instead of silk, and of leaving wounds open from twenty-four to forty-eight hours. He obtained the best results when the wound had been left open for twelve to twenty-four hours.

The results which Dr Babcock has obtained with wire have been excellent, so far as I have been able to note. I also have used it, but I am sure that fewer of my patients would have hernias today if I had employed silk. Nevertheless I do not believe that at this time it should be used indiscriminately.

DR CUTLER (closing). Dr Baldridge wrote me before this meeting to remind me that when his group of students worked in the dog laboratory they closed all layers with catgut. That was a good point. It represents the fact that in twenty-five years I have persuaded myself, if no one else that my results in all fields of work are better with silk than with catgut.

I appreciate fully the point emphasized by Dr Kelly that the technic is more important than the suture material. Fine silk breaks if the surgeon is rough. This has been emphasized repeatedly not only by Dr Hilsted in the early days but also by Allen Whipple, of New York City, who has been completely won over to the use of silk suture material in our own time. We often demonstrate to our house staff the superiority of silk over catgut by having the same operator utilize silk on one side and catgut on the other in the repair of a double inguinal hernia. One always finds more reaction in the catgut wound. The ideal conditions for perfect wound healing, which is the minimum reaction, are to be found when silk is used, although the operative technic of course plays a part.

Dr Kelly has objected to having to remove silk knots which are occasionally discharged even in uninfected clean wounds although he admitted that he might have fewer hernias if he used silk throughout. I may have a different point of view, for I would rather lay myself open to criticism from a patient who thought there was something wrong with the wound than have him undergo a secondary operation for hernia.

That foreign bodies can be tolerated in wounds we know well. In 1938 when I attended a surgical meeting in Brussels I spent a day and a half with Roux Berger at one of the great hospitals in Paris and to my consternation saw him bury French silkworm gut in wounds yet the wounds healed very well.

As to contamination I agree with Dr Baldridge that it is a matter of degree. The breaking down of a wound relates to the virulence of the organism and to the resistance of the host. Both these criteria may be altered by the presence of a foreign body.

Your president has said that he hasn't been sold yet on the use of silk. This reminds me of the attitude taken by our graduate students. Each year I give a course in technic to students in the graduate school, and they operate on animals and observe work in the hospital. Every year a number of them are won over to silk after what they experience and see. On their return home they write letters and say that if they use silk they may be the only persons using it in their communities and want to know whether if the silk sutures come out I will be willing to come and testify that it was a proper procedure.

EXPERIENCE WITH FEMORAL-VEIN LIGATION FOR PROPHYLAXIS OF POSTOPERATIVE PULMONARY EMBOLISM*

JOHN B. SEARS, M.D.†

BOSTON

UNTIL the enigma of postoperative thrombosis is solved, surgeons must be concerned with the prevention of pulmonary embolism. This is a report of the experience of the surgical staff of the Beth Israel Hospital during the last half year with 10 cases of deep peripheral venous thrombosis for which either the popliteal or femoral vein was ligated as a prophylaxis against embolism.

In recent years Homans¹⁻³ has written a great deal about thrombosis of the deep veins in the leg, and has stressed the sinister relation between bland thrombosis and pulmonary embolism; the cases reported by him were all ambulatory and were associated with minor injury or strain. All our cases occurred after operation.

This presentation is not concerned with the more familiar condition of iliofemoral thrombophlebitis (milk leg) and peripheral thrombophlebitis. In these there is likely to be an inflammatory reaction in the vein wall, a more marked clinical reaction, an adherent thrombus and, thus, less danger of embolism.

The syndrome now to be discussed is more treacherous. Clotting apparently begins within the veins among the calf muscles and may progress rapidly to the femoral region—or even higher. It is the loosely attached thrombus or its free-floating propagating tail that breaks off and journeys so dramatically to the heart and lungs.

The onset is usually mild and insidious, with little or no change in the chart. The patient sometimes complains of pain in the leg, usually in the calf region, occasionally in the heel. The pain varies in intensity from slight to severe discomfort. One of our patients, after an infarction, admitted mild pain in the calf of four days' duration, but had never complained of it to the house officers. The duration of the pain likewise varies. In most patients it lasts from two to eight days. The leg pain may disappear after several days, only to be followed by embolism or by pain in the femoral region, which signifies extension to the femoral or iliac vein.

On physical examination one finds tenderness on deep palpation of the calf muscles, and force-

ful dorsiflexion of the foot causes pain in the calf or popliteal region (Homans's² sign‡). A swelling of the leg or slight edema over the shin and ankle may occur while the patient is in bed—in 2 cases in our group of 10—and may be related to an inflammatory reaction. Cyanosis, even temporary, is rare. We have found no impressive evidence of sympathetic hyperactivity and have not done lumbar novocain injections.

In this series of 10 cases the sexes were equally divided. The ages varied from thirty-five to seventy, the average being fifty-one years. Ninety per cent occurred in the right lower extremity. The complication was associated with no particular type of surgery, having followed biliary-tract operations in 4 cases, hernia operations in 2 and operations on the stomach, on the colon, for ruptured intervertebral disk and for a gynecologic condition in 1 each.

The first manifestation of pain in the calf in this group appeared five to fifteen days after operation, the average being 11 days. The diagnosis of deep thrombosis was made after infarction or embolism in 3 cases.

I believe that deep thrombosis in the calf occurs more frequently but is less often recognized than iliofemoral thrombosis, and that the former is the more frequent source of pulmonary embolism. The diagnosis is obviously difficult in many cases, and is almost impossible in others.

Fortunately, deep thrombosis does not usually result in embolism. But because it may, and because we have witnessed several fatal embolisms during a waiting period of indecision, it is now our policy to divide and ligate the femoral vein as soon as possible after making a diagnosis of deep thrombosis in the leg. The vein is divided even if the diagnosis is made after infarction or embolism has taken place, for the accident is likely to recur.

Division of the vein removes the danger of embolism and prevents extension of the thrombotic process beyond the operative site. From the viewpoint of convalescence, the patient becomes ambulatory earlier. In our series the femoral vein was divided in 8 cases, the popliteal in 2.

The operation is performed under novocain infiltration, and a vertical 10-cm. incision is made in the femoral triangle over the femoral impulse. The

‡"There is a sense of discomfort when the tendo Achillis is put upon the stretch by forced passive dorsiflexion of the foot. The discomfort is felt back of the upper calf and knee."

artery is exposed, and the vein is found under it in the upper part of the wound. Several large tributaries, including the profunda vein, are usually seen. The following conditions may be present:

The vein may appear and feel normal. A silk ligature is tied just distal to the profunda vein, or any other large tributary, and the vein is opened below this point. The amount and speed of hemorrhage should be some indication of the extent of venous occlusion. In some of these patients, I have injected an opaque solution (Diodrast) into the distal end of the severed vein in an attempt to visualize the upper end of the thrombus by immediate x-ray films. Usually a section of the vein was removed for microscopic study.

The vein may contain a soft unattached thrombus. This is gently removed with a suction tip introduced through a small longitudinal incision.

The vein may be firmly thrombosed and may be surrounded by inflammatory exudate. In this situation the operation is without prophylactic value. Since this thrombophlebitis is considered the source of a vasospastic reflex,^{4, 8} which is one of the most important factors in the production of the clinical manifestations, a portion of the involved vein should be resected.

Homan's sign, when present, has persisted from two to six days after operation and in fact may become more intense. The temperature and white cell count may also rise after operation. Once the diagnosis has been made the extremity is elevated, and this position is maintained after operation. If there are no general contraindications, I permit the patient to get out of bed in a few days, and I have advised the subsequent use of woven bandages because of the tendency to slight swelling in ambulatory cases.

CASE REPORTS

CASE 1 M C (B I H 50003), a 70-year old man, was operated on for an incarcerated inguinal hernia on November 18, 1939. Nine days later he sat in a chair. On the following day, he complained of pain in the right calf. Examination showed deep tenderness and a positive Homan's sign. There was no fever or swelling. The condition was diagnosed as a deep thrombosis, and femoral vein ligation was recommended and refused. On the 12th postoperative day, the temperature rose. Three days later, in searching for the cause of this fever, it was noted that the calf tenderness and pain had disappeared, but distinct tenderness could be made out in the right femoral triangle. There was no edema anywhere. The patient agreed to surgery. The femoral vein was found to be thrombosed and was surrounded by an organizing exudate. A biopsy specimen of the vein was taken. The temperature became normal in 48 hours, and the patient went home 4 days later.

The pathological report (S39 2496) read 'Beginning organization

Comment. This case is of interest because of the sequence of events. The original findings in the right leg were typical of bland thrombosis. Five days later the process had extended to the upper thigh, and was associated with fever but no pain. The operation at this time was without prophylactic value because the thrombus was already retracted to the vein wall at the level of the operation.

CASE 2 C W (B I H 49274), a 35 year old woman, on October 3, 1939, had a cholecystectomy performed under Nupercaine anesthesia. She dangled her legs on the 11th day, and was up in a chair on the 12th. She was discharged afebrile on the 13th day. She was readmitted 2 days later with severe pain in the right calf of 24 hours' duration. Physical examination showed marked tenderness in the right calf plus pain on dorsiflexion. The white cell count was 10,000. She was immediately operated on. Division and ligation of the right femoral vein were done with injection of Diodrast. The pain in the calf persisted for 5 days, and she was discharged 12 days after operation, wearing an Ace bandage. There was no swelling.

The pathological report (S39 2182) read 'Negative vein.'

The x-ray report (79999) was 'Injected fluid stops abruptly 3 cm below the division of the vein below the knee.'

Comment. This patient was a physician who diagnosed her deep thrombosis. The prophylactic ligation afforded great mental comfort and assured early rehabilitation. Four months later she reported slight swelling unless she wore a woven stocking.

CASE 3 H O (B I H 49256), a 47 year old married woman, underwent a cholecystectomy on September 30, 1939, under Nupercaine anesthesia. On the 11th day after cholecystectomy she dangled her legs. That afternoon the temperature rose to 100.2°F, the pulse to 130 and the respirations to 30. There was slight difficulty in breathing. The patient complained of a heaviness over the breast bone, like a cold coming on. The next morning the pulse, temperature and respirations were normal. At 4 p.m. she suddenly went into collapse and was placed in an oxygen tent. The blood pressure was 45/30. She was in shock most of the evening and received oxygen, pipavrine and atropine. The next morning (the 13th day after operation) there was tenderness in the right calf and the patient admitted that she had had some pain there for 4 days. She was taken to the operating room in bed and wearing an oxygen mask. The right femoral vein was exposed and divided. She was discharged well on October 29, 1939, 30 days after the gall bladder operation.

The x-ray report (79866) on October 13, 1939 was as follows: 'Pulmonary infarction.'

Comment. The first infarction was mild but was followed in 24 hours by the severest nonfatal embolism in this series. This might have been prevented if the legs had been examined for deep tenderness. The pain in the right calf had been so moderate that the patient had not bothered to report it.

SUMMARY

Failure to divide deep veins containing bland clots may result in major catastrophes. I believe that some of the operations in this small series prevented embolism and therefore justified those

which may have been unnecessary. Earlier rehabilitation has been the rule.

This experience with a perplexing group of cases is presented in the hope that interest in the problem involved—diagnosis and treatment—will be intensified. Further clarification and evaluation are needed.

MEDICAL PROGRESS

SYPHILIS

C. GUY LANE, M.D.,* AND G. MARSHALL CRAWFORD, M.D.†

BOSTON

THE usual large number of articles on syphilis appeared during the past year, many of which cannot even be touched upon in this review. We are entering an era in which the public-health aspects of this disease will play an extremely important part as the armed forces of the nation gather in increasing concentrations in the various camps throughout the country. At the same time, the private physician continues to play a leading part in the detection and control of syphilis.

PUBLIC HEALTH

The role of the private practitioner in controlling syphilis has recently been discussed by Stokes.¹ He believes that local physicians are co-operating well in the control campaign, but also points out that if co-operation fails, the taking over of the problems of syphilis by the state is inevitable. It must provide diagnostic mechanism, drugs and equipment needed for treatment, and must inevitably supply the epidemiologic contact-tracing service (Massachusetts does supply this service). Stokes also believes that the practicing physician should be provided with dependable consultation and should keep medical control of the patients whom he refers. Certainly if the state provides these aids, the medical fraternity should be able to co-operate to the fullest extent in return. A serologic consultation service is already being maintained in some states. Vonderlehr² writes in a similar vein.

Syphilis in industry has received a great deal of attention. Russell³ stresses the economic as well as the social problem. Since there are over 15,000,000 workers in the mining, metal and manu-

facturing trades in the United States, this author points out that a syphilis program covering this group and their families would reach about half the people of the country. Such a program is a colossal task, to say the least. Education may well play the most important role. Elimination of syphilis from industrial workers will not only prolong their lives but make them better producers. A step in this direction was made in the cogent syphilis-control program reported by Wilzbach.⁴ A Cincinnati industrial leader formed a committee of his colleagues to promote the examining of employees for syphilis. Routine blood testing revealed an incidence of 44 cases per 1000 in contrast to only 6 per 1000 discovered when checked on suspicion only. An inexpensive plan was worked out which is paid for by the employer. Only the doctors and the worker know the result. Co-operation by the labor unions was procured. So far no employee in Cincinnati has lost his job on account of a positive serologic report. Educational lectures are preliminary and follow-up features. Many plants adopted a blood test as part of examination at the time of employment, but with the agreement that syphilis was not sufficient grounds for rejection of an applicant. It is obvious that certain qualifications as to the infectiousness and disabling lesions are bound to modify this agreement.

Edwards and Kinsie⁵ have called attention to illegal and unethical practices extant among pharmacists. A survey of 1151 drugstores in 35 cities revealed that only 7 per cent of these refused either to diagnose or to sell so-called "remedies" for venereal diseases. This widespread practice, the many charlatans and various unlicensed practitioners are responsible for a great many improperly treated cases. The authors believe that action

*Clinical professor of dermatology, Harvard Medical School, chief, Department of Dermatology, Massachusetts General Hospital.

†Assistant in dermatology, Harvard Medical School; assistant in dermatology, Massachusetts General Hospital.

to offset these factors should include the suppression of illegal drugstore activity, the eradication of quackery in medicine and the education of the public. Numerous other reports bear witness to the existence of state-wide campaigns in the proper direction.

An interesting report on the follow-up of cases of early syphilis from the prearsphenamine era is that of Willners.⁶ Six hundred and sixteen patients seen in Stockholm in 1912 and 1913 with early syphilis received mercury, only, and in later years an occasional injection of other drugs. Three fifths of these patients were living and traced in 1938. An adequate comparison of the effect of therapy was not feasible, but the death rate of the entire group was found to be 32 per cent higher than that among the general population.

The annual report of the Surgeon General of the United States Navy⁷ for 1938 is of interest. Removal of punitive measures imposed on enlisted men contracting venereal diseases revealed an increased incidence of 21.2 per cent. This probably represents the true number of cases. The average patient was sick 2.6 days less, however, and there were fewer complications. Educational work is being increased among enlisted men and may in time reduce the incidence of disease.

IMMUNITY

There are some who maintain that early syphilis should be allowed to go through the secondary stage before treatment is instituted. This theory must be held in abeyance, however, until more is understood about immunity in syphilis. A notable step in the study of immunity is reported by Turner,⁸ who found that syphilitic rabbits develop humoral antibodies to syphilis during the course of their infection. Kemp,⁹ reviewing immunity in syphilis, calls attention to the fact that it is slow in development and does not become evident until the infection has been present for some weeks. Treatment instituted before the immune stage is established may abruptly terminate, or at least delay, its development, and leads to recurrences. Kemp states that late syphilitic lesions are evidence of breakdown in immunity. The difference of immunity maintained by various tissues determines the incidence of later manifestations of syphilis. The Negro race has a high degree of immunity except for the tissues of the cardiovascular system. Women have a stronger immunity than men; Kemp's studies indicated that the female sex hormone may be responsible for this. There are no other definitely known factors which influence immunity in syphilis.

SEROLOGY

There is a continued attempt on the part of the Committee on the Evaluation of Serodiagnostic Tests for Syphilis to improve the quality of procedures performed in the state laboratories. The report of this committee for the years 1938 and 1939¹⁰ indicated that the control serologists are maintaining high standards. Whereas thirty state laboratories were unsatisfactory in 1938, only twenty-two were in this category in 1939. The maintenance of high standards by the control serologists in the state laboratories permits a proper checking and evaluation of the performance of the numerous local laboratories.

The Davies-Hinton test for the examination of cerebrospinal fluid is proving fully satisfactory. Brenner¹¹ reports close agreement of the Davies-Hinton and the Wassermann tests on 2110 consecutive cerebrospinal-fluid examinations. In cases of disagreement the former was found to be slightly more reliable than the latter.

Continued attempts are being made to eliminate the false-positive problem from serologic tests for syphilis. Mohr and Smith¹² studied the supposed daily variations of the reagin content of syphilitic serum, and believe that a fluctuating sensitivity of the tests employed is reflected. They think that the quantitative flocculation technics are valuable in eliminating false-positive reactions in questionable cases. They seriously doubt the value of the provocative test for syphilis. Ingraham and Mayer¹³ investigated the effect of the menstrual cycle on the blood serologic test for syphilis. They concluded that false-positive tests during the menstrual period must be a peculiarity either of the individual patient or of the test employed, and are not due to blood changes present in all women.

Quantitative serologic tests for syphilis are being developed with gratifying results. Greene and his associates¹⁴ report a quantitative study of syphilitic serum with Hinton and Kline tests which gives information indicating reagin titers and eliminates zone reactions. Kahn¹⁵ describes a newly developed serologic verification test, which is a modification of the standard Kahn technic. This should help to detect false-positive tests in questionable cases. This test is intended only as a supplementary procedure to the usual diagnostic tests in doubtful asymptomatic cases.

Another step toward increasing the specificity of serologic tests for syphilis is the development of the spirochete complement-fixation reaction. Eriksenn and Eagle¹⁶ have compared this reaction with the Eagle flocculation and Wassermann procedures. Phenolized cultures of a standard spiro-

chete strain have been found to give positive complement-fixation reactions with syphilitic serums. These authors believe that there is at least a potential superiority in this reaction.

Acute infections have long been thought to be responsible for some temporarily false-positive reports obtained with serologic tests for syphilis. Clifton and Heinz¹⁷ report the finding of 82 children with false-positive or doubtful reactions out of 5620 new patients examined in one year's time at a children's hospital. An acute infection or a severe generalized cutaneous eruption was present in 74 of these patients. These serologic tests returned to normal before or soon after evidences of infection cleared.

Moore¹⁸ has suggested a method of approach to the recognition of the biologic false-positive serologic tests for syphilis. The full text¹⁹ is more than worthy of careful study by anyone faced with this problem. The quantitative serologic test,¹⁴ the Kahn verification test¹⁵ and the complement-fixation test with spirochetal antigen¹⁶ are among the suggested procedures. Although such tests require special laboratory facilities, they may be essential to the solution of some of these cases. It is emphasized that the final decision is a highly individualized problem requiring weeks or months of observation and expert advice. The oft-repeated but pertinent adage that no treatment should be instituted without a definitely established diagnosis still holds.

CLINICAL PROBLEMS

An old and mistaken tenet has been dispelled by Shaw.²⁰ It was often stated that an extensive cutaneous syphilide provided immunity which protected the central nervous system from syphilis. Shaw's report deals with 70 patients exhibiting cutaneous or mucous-membrane syphilides or syphilis of the bones, or both, of which 15 (21 per cent) had neuraxis involvement. All 15 patients had positive cerebrospinal fluids; 7 exhibited symptoms of neurosyphilis. It is obvious that this type of case as well as all others should have routine lumbar punctures. These findings corroborate the experience of most present-day syphilologists.

A review by Dyar and Dalton²¹ describes sixteen different manifestations of syphilis in the eye. According to their statistics syphilis comprises 2 per cent of all eye disease. These various lesions are well described, and the plans of treatment outlined agree with accepted programs of therapy. The importance of syphilis in diseases of the nose and accessory sinuses is emphasized by Smith.²² After describing the recognized syphilitic lesions of these structures, he emphasizes that several non-syphilitic diseases of the nose and sinuses may

have a syphilitic background that retards their response to customary therapy. It is emphasized that surgery of the nose and sinuses in the presence of syphilis may be followed by a prolonged and unsatisfactory healing period, with a high incidence of secondary infection and excessive scar formation. Syphilis of the stomach is reviewed by Williams and Kimmelstiel.²³ Although uncommon, this lesion should not be lost sight of by physicians in dealing with gastrointestinal complaints, and should not be confused with a penetrating ulcer in a syphilitic patient. It should be strongly suspected when a comparatively young person is found, by x-ray examination, to have a smooth, funnel or tube deformity of the stomach accompanied by other stigmas of syphilis. It is difficult to establish the diagnosis definitely, since the response to treatment is very slow.

So-called "latent" syphilis continues to be an engrossing problem. A paper by Cormia and Lewis²⁴ deals with the interpretation of the factor of latency. It is stated that latency is generally assumed to indicate a dormant or inactive process, although this rarely happens. The minimum requirements for the diagnosis of latency include a negative physical examination, normal cerebrospinal fluid and a normal fluoroscopic appearance of the heart and great vessels. The authors state that of all cases in which the diagnosis of latent syphilis is made, 30 per cent will subsequently develop signs of activity. Latency may be clinical, pathologic or serologic; yet these phases are relative, rather than absolute, fixed states. An interesting report by O'Leary and Williams²⁵ deals with the duration of infectiousness of syphilis. It has been a widely used rule of thumb that five years after the acquisition of syphilis the disease is not transmissible regardless of therapy. One thousand one hundred and seventy-five married couples were studied by these authors. At least one of each pair had syphilis, and the conjugal transmission of the disease was interpolated. It was concluded that syphilis may be considered infectious during the first five years of the disease, and that although each year thereafter diminishes the possibility of transmission, the likelihood of conjugal infection does not approach the vanishing point until the tenth year.

CARDIOVASCULAR SYPHILIS

Numerous reports regarding cardiovascular syphilis continue to appear, and they support the previously established concepts of the disease. The great value of adequate routine therapy in preventing cardiovascular syphilis is borne out by statistics. Administration of antisyphilitic treatment after the discovery of syphilitic heart disease should

be carried on carefully within the range of tolerance of the individual patient. Only in the most advanced type of syphilis of the aorta (syphilitic aortic insufficiency and extensive aneurysm formation) is the outlook dim in spite of adequate treatment. The period of life expectancy in these cases, according to Kampmeier and Combs,²⁶ is not appreciably extended by antisyphilitic treatment. Of the other factors influencing the duration of life, cardiac decompensation is the gravest. Manual labor was shown to accelerate the progress of syphilitic aortic disease.

NEUROSYPHILIS

By now it is surely an accepted dictum that every patient afflicted with syphilis should have a cerebrospinal-fluid examination, sooner or later, according to the stage of disease present when the case comes under observation. Headache following lumbar puncture is a deterrent in many cases. The time consumed and the expense of hospitalization increase the reluctance of both patient and physician. Kulchar²⁷ believes that cisternal puncture eliminates these objections. He has done 1246 cisternal punctures on 960 ambulatory patients, 80 per cent of whom had no reactions whatever. The usual postpuncture type of headache and occasional pain and stiffness in the cervical region were essentially the only complications encountered. It should be stated that although Kulchar's figures are optimistic, cisternal puncture is not a procedure for casual use by the inexperienced. The skill of a practiced operator is required, and the fact that a fatality can result by puncturing the medulla or dural vessels should serve as adequate warning.

The so-called "tabetic cord bladder" is discussed by Emmett,²⁸ who promulgates new and very rational concepts. It is pointed out that true incontinence is uncommon, there being merely an overflow from a distended bladder or urgency from urinary infection which has been initiated by urinary retention. In many cases it is difficult to tell whether the atonic bladder or an obstruction of the vesical neck is the primary factor. The author goes so far as to say that many cord bladders are really cases of simple obstruction of the vesical neck in which tabes dorsalis plays little if any part.

CONGENITAL SYPHILIS

A new book on congenital syphilis has been published by Dennie and Pakula,²⁹ covering the subject efficiently and in more detail than has been before attempted.

Last year's progress report³⁰ recommended the full perusal of a paper by Black on the diagnosis

of congenital syphilis. This author has condensed the same material in a more recent publication,³¹ which is again to be commended. This is a very concise contribution which will not be quoted because of its brevity and ready availability—it was distributed to all the members of the Massachusetts Medical Society.

According to some authorities, congenital syphilis has been responsible for much mental deficiency. This has not been the experience of syphilologists as a whole, however, and a recent report by Hays³² is enlightening. A review of statistics covering 22,313 cases of feeble-mindedness revealed syphilis in only 4.83 per cent of institutional cases. This is not a high percentage. The high death rate among congenital syphilitic infants may remove many potential feeble-minded cases. On the other hand, perhaps many of these patients would have been feeble-minded without the presence of syphilis. The United States Public Health Service³³ has published its seventh supplement to *Veneral Disease Information* entitled "Syphilis in Mother and Child." This brochure covers the problem of syphilis in the pregnant woman in a concise but most instructive manner, and includes congenital syphilis handled in the same fashion. This and the previous supplements mentioned in preceding syphilis progress reports are obtainable for an extremely modest sum, and should be most useful as a brief outline for the general practitioner.

The controversy regarding the value of acetarsone versus the usual injection therapy for syphilis in children continues unabated. Pediatricians seem to favor the former and syphilologists the latter. The situation has been summarized in an editorial.³⁴ The consensus seems to indicate that results can be obtained with the oral administration of acetarsone in congenital syphilis. It is pointed out, however, that the uncertainty of proper dosage and of administration is a serious deterrent.

There is a tendency among some writers to hold that all offspring of syphilitic mothers who did not receive adequate therapy for syphilis during pregnancy should be routinely treated for syphilis. This dictum we would distinctly deprecate. Many of these infants, if carefully followed, will be found to be free of the disease. The maxim that treatment for syphilis should not be instituted until the diagnosis is unequivocally established is fully as applicable in congenital disease as in the acquired form.

Roentgenographic evidence in the bones of the newborn holds a justly established place in the diagnosis of congenital syphilis. Christie³⁵ has

shown, however, that administration of bismuth to the pregnant woman may be responsible for possibly misleading shadows in the x-ray plates of the bones of the offspring. He points out that since conditions other than syphilis may bring about roentgenographic changes in the bones, confirmatory evidence of syphilis is the more important. Whitridge³⁶ clarified this problem by the administration of weekly injections of bismuth salicylate in oil in the customary dosage for not more than eight injections during the last trimester of 12 nonsyphilitic pregnant women. Roentgenograms taken within the first week of life showed definite roentgenographic changes near the ends of the long bones in 9 infants, consisting of transverse bands of increased density. Evans³⁷ points out that the presence or absence of osseous lesions, as well as other evidence of syphilis, depends on the length of time of infection of the fetus prior to delivery. Thus a child born free of all manifestations of congenital syphilis might not develop such evidence for several weeks or months after birth. This author emphasizes the possibility of making a false diagnosis of syphilis from improper interpretation of changes occurring in the metaphyseal areas which may be due to several nonsyphilitic conditions. In the second or third month of life these changes may become detectable and can be most confusing.

Ariboflavinosis has been found to cause corneal lesions similar to interstitial keratitis. Kruse et al.³⁸ found that riboflavin hastens response to arsenical therapy in syphilitic interstitial keratitis, and speculated on the possible interrelations.

THERAPY

In the field of treatment for syphilis the past year has been productive of the usual reports on various new drugs, the follow-up of studies on drugs already in use and the results obtained. These statistics are in agreement with previous publications and do not warrant further comment.

Hyperpyrexia is the treatment par excellence for some forms of neurosyphilis, notably dementia paralytica. A great burden would be lifted if more fever therapy could be carried out before such cases reach the degenerative stage. Hyperpyrexia, however, is fraught with too many pitfalls, and the incidence of fatalities, even under ideal hospital care, is still sufficiently high to make it too hazardous a procedure to be regarded lightly.

A long-range comparison of malarial and artificial fever in the treatment of paresis is reported by O'Leary and his associates.³⁹ An evaluation was made of the clinical and serologic results of these two types of fever therapy in 1100 malarial treated cases and 320 patients who received arti-

ficial fever. With either form of therapy the chances of clinical remission were 1:2 in mild cases and 1:4 in intermediate cases. In severe paresis only a 1:100 chance was provided by malaria, whereas artificial fever offered a 1:10 chance. It cannot be overemphasized that the sooner treatment is instituted the better the outcome. The crude death rate within three months of the time treatment was instituted was 13 per cent with malaria and 8 per cent with artificial fever. When complete remissions were attained with either form of therapy, they were maintained in 95 per cent of the cases. Both blood and cerebrospinal-fluid serologic results roughly parallel the clinical results. It was found that malaria combined with chemotherapy provided twice as many remissions. A negative blood serologic test was conclusively shown not to indicate the status of the cerebrospinal fluid.

Brunsting and Love⁴⁰ report a useful finding in the tempering effect of bismuth on therapeutic malaria. It was found that 0.1 gm. of sodium bismuth thioglycollate (Thio-bismol) has a definite controlling influence on the sequence of paroxysms of therapeutic malaria. This finding is of especial practical value in those cases in which there is a prolonged slow prodromal rise in temperature and in which a double tertian strain gives rise to daily paroxysms. Following a single injection of Thio-bismol these cases settle down to the usual cycle, with a paroxysm every other day. The severity of malarial therapy can thus be tempered to the tolerance of the patient, and this modality can be applied to a wider range of cases. Cole and his associates⁴¹ corroborate the findings of the preceding authors. The death rate can be distinctly reduced by employing this procedure. Both reports point out that Thio-bismol is not offered as a substitute for quinine in terminating malaria. Repeated injections of bismuth stopped therapeutic malaria for long periods but did not cure it.

The treatment of neurosyphilis in parallel series of 256 cases by Tryparsamide and 314 cases with sodium succinyl-methylamide-p-arsenate (Neocryl) is reported by Ross.⁴² The standard dose of each drug was 3.0 gm. given intravenously at weekly intervals. Twelve months after the end of treatment the results obtained with Neocryl were in no way inferior to those of Tryparsamide. Seventy-eight cases (30 per cent) of those treated with Tryparsamide exhibited toxic manifestations, whereas only 27 cases (9 per cent) of those treated with Neocryl had toxic reactions. It was chiefly in its relative innocuity to the optic nerve that the advantages of Neocryl became apparent. Over half the unfavorable reactions to Tryparsamide were ocular, and 3 cases of complete blindness developed.

Necroly was accountable for only 1 case of visual damage. If this drug is as effective and at the same time as innocuous as this report indicates, it will indeed be a most beneficial boon. Further study is certainly warranted.

Massive-dose intravenous chemotherapy of syphilis, the so called "five day treatment," has been carried on by its instigators. The Council on Pharmacy and Chemistry of the American Medical Association¹³ commends this work for its great possibilities. The frequency of toxic reactions, some of them grave in type, requires the adoption of a conservative attitude, however. The council believes that this form of syphilis therapy is still in the experimental stage, and should be confined to large university and public health clinics or suitable hospitals organized to carry out this project on a recognized experimental plane. Current editorial comment¹⁴ is in full agreement with this opinion. In last year's report¹⁵ we suggested an observation period of ten or fifteen years before final results can be evaluated. There is no reason to change this criterion. Although massive-dose arsenotherapy may prove to be of major importance, the factors of drugs, duration of treatment and elimination of toxic recurrences remain as obstacles. A more suitable type of drug may yet be found, or more effective combinations of existing drugs may prove more satisfactory. It is certain that if these procedures are properly worked out, the economic implications alone will be of tremendous importance.

TREATMENT REACTIONS

An interesting paper by Epstein¹⁶ reports the cases of 2 industrial workers with previous symptoms of plumbism who suffered recurrences following the administration of bismuth for syphilis. The question was raised as to whether bismuth replaces lead stored in the bones, thereby mobilizing the latter. The implication of this report in regard to industrial syphilis is obvious. A possible clue to the mechanism of this phenomenon is found in the report of Corson and his associates,¹⁷ who found that the administration of ammonium chloride brought about the mobilization of bismuth. An increase in the urinary output of calcium accompanied this excretion. The urinary calcium is apparently drawn from the bones, for the blood calcium was not affected. Since calcium and lead are known to be deposited and eliminated in parallel, it is suggested that possibly calcium and bismuth also act similarly. Should this be so, it would explain the effect of bismuth on latent plumbism, as reported by Epstein. An interesting conjecture comes to mind as to the possible effect of ammonium chloride on bismuth stomatitis.

Early acute arsenical erythema ("erythema of the ninth day") are becoming more widely recognized. Thomas and Cañizares¹⁸ report 2 cases in which a second erythema occurred following the later administration of arsenic. It is recognized that in the majority of cases in which an uncomplicated ninth day erythema occurs, subsequent administration of the arsphenamines is satisfactorily tolerated.

Blood dyscrasias following arsenical injections were studied by Falconer and Epstein,¹⁹ who found that 5 of 6 patients developing thrombopenic purpura from arsphenamines could tolerate Mapharsen. These authors believe that allergy is back of these reactions. They found vitamin C to be useless. Leukocyte and platelet counts of the peripheral blood were depressed more by the arsphenamines than by Mapharsen.

A review by Stephenson and Chambers²⁰ of the toxic effects of arsenical compounds as used in the United States Navy throws interesting light on several drugs. There were forty reactions of various types among 123,176 doses. The relative occurrence was as follows: acetarsone 1/26, neosarsphenamine 1/2240 and Mapharsen 1/6108. There were 3 deaths, all with neosarsphenamine. Arsenical dermatitis in some form occurred in 62.5 per cent of the above reactions. Schoch et al²¹ studied the use of Mapharsen following dermatitis from the arsphenamines. They found that the drug could usually be administered successfully to these patients only if their eruptions had been less severe than a generalized exudative exfoliative dermatitis which required hospitalization.

Liver damage from arsenical compounds received considerable emphasis in the past year. Rankin and Marlow²² studied the extent of liver damage after recovery from postarsphenamine jaundice. They believe that the bulk of the evidence favors the opinion that arsenic has a definitely toxic effect on the liver, but that it more often acts jointly with other factors. Severe arsenical reactions and subsequent alcoholism gave rise to the greatest amount of damage. It is obvious that further arsenical therapy in such cases should be pursued with caution.

The effect of diet in guarding against liver damage from the arsphenamines was studied by Messinger and Hawkins.²³ A high protein diet was found to be the most effective prophylactic measure, a high carbohydrate diet was also beneficial though not so uniformly protective. A high fat diet was found to be deleterious, and some of the animals on this regime developed a progressive liver injury, with intoxication which proved fatal.

CASE 27031*

PRESENTATION OF CASE

A baby girl entered the hospital at the age of eleven hours because of jaundice noted one hour after birth.

The family history revealed that the first child died at one month of age of "indigestion"; the second child was living and well; the third child, a boy, died on the first day of life of "yellow jaundice." There was no history in the parents' families suggestive of blood dyscrasia. The mother was well during pregnancy except for edema during the last three days. The child was born at home, by a normal delivery, with a birth weight of 5 pounds, 8 ounces. There was no difficulty in resuscitation, and no jaundice was noted at birth. The vernix was white, and the placenta apparently normal. A large amount of yellowish amniotic fluid was said to have been present. After one hour, the baby was found to be cold and yellow, and the attending physician advised hospitalization, with a diagnosis of "bile-duct obstruction."

Physical examination revealed a well-developed and well-nourished female infant who was extremely hypotonic, brownish yellow and cyanotic, and who appeared moribund. The skin was dry, the extremities cold, and the respirations very shallow. The vernix behind the ears and between the labia was white. The fontanel was not full or bulging. The scleras and conjunctivas were yellowish brown, but no petechiae were found; nor were petechiae present on the skin or mucous membranes. Examination of the lungs was negative. Examination of the heart showed a diffuse apical impulse, which was felt maximally to the left of the mammary line. The heart was enlarged to percussion, but the sounds were of good quality, with a rapid rate and regular rhythm. A systolic murmur was present, heard best at the apex and terminated by a sharp second sound. The abdomen was moderately enlarged, with hypotonic musculature. Both liver and spleen were greatly enlarged, with the lower margins palpable

at the iliac crest laterally; the spleen was approximately 5 cm. wide and of rather firm consistence. The extremities were hypotonic almost to the point of flaccidity, but there was no edema.

The temperature was normal, the pulse 142, and the respirations 16.

Examination of the urine showed it to be brown with a ++ test for albumin and a ++ test for bile. Microscopically there were occasional white cells and many epithelial cells. Examination of the blood showed a red-cell count of 2,300,000 with a hemoglobin of 68 per cent, and a white-cell count of 320,000 nucleated cells, of which approximately 303,000 were of the erythrocytic series. A blood film showed marked macrocytosis, hypochromia and polychromatophilia, and large numbers of all types of the red-cell series from extremely primitive bone-marrow cells down to erythrocytes. The clotting time of the blood was 2 minutes, and the bleeding time longer than 15 minutes.

Fluoroscopy revealed marked cardiac enlargement, with feeble heart action.

The patient received a transfusion of 60 cc. of citrated whole blood, and her color improved. Approximately eight hours after admission, a second transfusion of 30 cc. of whole blood and 30 cc. of 10 per cent glucose were given. The patient was maintained in an oxygen tent throughout. The following morning her condition remained poor; the skin was yellow, and the respiratory rate 16 to 18 per minute. She refused to suck and responded poorly to stimulants. The red-cell count was 3,400,000 with a hemoglobin of 75 per cent, and the white-cell count 280,000 nucleated cells, of which 266,000 were of the erythroblastic series. Digifolin, 1.5 gr., was given intramuscularly without significant effect, the apical beat falling from 142 to 136. The child could not be roused by stimulation, the temperature began to fall, edema of the skin and subcutaneous tissues was noted and the lungs became increasingly congested with many moist rales. A lumbar puncture yielded 3 cc. of xanthochromic fluid, which contained 12 red cells and 3 nucleated cells per cubic millimeter; the Pandy reaction was faintly positive, the serum van den Bergh indirect, the sugar content normal, and the total protein 110 mg. per 100 cc., with no growth on culture. The respirations and heart rate gradually slowed, and Coramine was given with no effect. For the last half hour of life the heart beat very slowly and irregularly and the respirations were gasping, occurring in series of two or three in Cheyne-Stokes fashion. The child died twenty hours after admission. Terminally the carbon dioxide combining power of the blood was 47.6 vol. per cent, the nonprotein nitrogen 66 mg.

*This case is presented through the courtesy of the Children's Hospital, Boston.

per 100 cc., the serum protein 4.8 gm., and the serum sugar 95 mg.

DIFFERENTIAL DIAGNOSIS

DR. LEO B. BURGIN: We have a newborn infant who entered the hospital in a moribund condition with a history of jaundice starting immediately after birth, with enlarged heart, liver and spleen, and a blood picture showing anemia and unusual erythroblastic activity. This case presents a new experience in these exercises, a family history that is relevant. There are a number of disorders and syndromes in the neonatal period that might account for some of the findings.

Infection with sepsis, whether acquired or antenatal, can give such a picture in the newborn. Signs of infection precede as a rule the signs of a disturbed hematopoietic system. Since there is no evidence of fever, vomiting or diarrhea, and no evidence of an acquired disease process, we can dismiss this cause.

Congenital malformation of the bile duct must be considered. It would give rise to the severe degree of jaundice that was observed in this case. However, the jaundice at birth is usually slight, but with the passage of time becomes severer. We should not expect to find this degree of erythroblastic activity during the neonatal period. We might expect 1000 or 2000 nucleated red cells per cubic millimeter, but not 200,000 or 300,000. In addition, congenital malformation of the bile ducts would hardly explain the presence of an enlarged heart.

From the laboratory data we have no evidence of blood dyscrasia—leukemia, aplastic anemia or familial hemolytic jaundice. The family history of jaundice is suggestive, but although hemolytic jaundice is described in the neonatal period, it is not common, and it would be unusual to find two neonatal cases in one family. In addition, there is no marked erythroblastic activity with hemolytic jaundice.

We might suppose a combination of two things, although we should like to explain everything by one diagnosis. The infant might have had congenital malformation of the heart, with icterus neonatorum. Jaundice in the newborn usually occurs after two or three days, is usually not so intense, and is not associated with marked enlargement of the liver and spleen; moreover, it is not associated with such large numbers of young red cells in the peripheral blood.

I think there are two conditions that could explain all the findings—congenital syphilis and erythroblastosis fetalis. In some cases syphilis can give rise to the symptoms noted here: enlarged

liver and spleen, large numbers of young red cells in the peripheral blood and enlargement of the heart. In this case, the presence of a white vernix caseosa and normal placenta is somewhat in favor of such a diagnosis. The family history is suggestive but not typical of what one expects in a family with syphilis. I have not forgotten that five or six years ago I admitted a child with a diagnosis of erythroblastosis of the newborn in whom Dr. Mallory demonstrated treponemas in the liver and other organs. The clinical picture seemed typical of erythroblastosis fetalis. However, in congenital syphilis, I do not believe that the erythroblastic picture starts so early as this—on the eighth or ninth day perhaps, but hardly at the beginning.

My diagnosis is erythroblastosis fetalis. The blood picture is typical—anemia, a color index greater than one, macrocytes in the peripheral blood, a large number of nucleated red cells and a prolonged bleeding time. The family history is distinctly in favor of such a diagnosis, as is the severe degree of icterus. The enlarged heart is a common finding in erythroblastosis fetalis. The absence of a golden vernix and enlarged placenta is a slightly discordant note, but we know that erythroblastosis fetalis can occur in a number of forms.

When edema is a prominent symptom we have “universal edema of the newborn”; when icterus is the prominent feature we have “icterus gravis neonatorum”; when anemia is marked, “congenital anemia of the newborn.” All degrees of the disorder may occur, so that we may expect that some cases will not have a golden vernix caseosa. The amniotic fluid is described as “yellow.” I shall keep my diagnosis of erythroblastosis fetalis.

As to the cause of death, I think it was cerebral in origin. The patient had Cheyne-Stokes respiration, the heart continued to beat for a half hour, and the respirations were rather diminished. Whether the cerebral signs were due to hemorrhage or to the presence of icterus, it is difficult to say. A spinal tap showed xanthochromic fluid, which suggests hemorrhage. On the other hand, the color might have been due to the presence of large quantities of bile in the spinal fluid. There were not a great many cells. If hemorrhage occurred in the first twenty hours, I think one ought to expect the presence of many more red cells than are reported in this case. The presence of an indirect serum van den Bergh suggests hemorrhage. There was no growth on culture, and no evidence of infection in the central nervous system. We know that, in erythroblastosis fetalis, icterus can involve the nuclei of the brain and give rise to cerebral symptoms. That, rather than

actual hemorrhage, probably was the cause of death; although hemorrhage can occur in erythroblastosis fetalis, it is usually petechial in type. We have here a prolonged bleeding time, and I see no reason why there should not have been hemorrhage into the brain.

The occurrence of edema terminally might have been due to failure of the heart. On the other hand, it might have been a part of the picture of erythroblastosis fetalis, with the anemia and poor oxygen carrying power of the nucleated red cells resulting in damage to the capillaries, in loss of fluid into the tissues and in consequent edema. The blood chemical findings were probably due to the fact that the child was dying, but here again we might explain the increased nonprotein nitrogen as due to impairment of the kidney function because of large areas of extramedullary hematopoiesis that occur in this disease. The liver, kidney and other organs show large areas of blood formation, and these may interfere with normal function. My diagnosis is erythroblastosis fetalis.

DR. ELI ROMBERG: Do you think there is a possibility of congenital heart disease superimposed on this picture, such as an open foramen ovale?

DR. BURGIN: That is possible. Murmurs in newborn infants are not reliable. Systolic murmurs have been described in a great number of cases with this condition, and I should like to explain the whole thing on one diagnosis.

CLINICAL DIAGNOSIS

Erythroblastosis fetalis.

DR. BURGIN'S DIAGNOSES

ANATOMICAL DIAGNOSES

Erythroblastosis fetalis.

Kernicterus.

Edema and congestion, generalized

PATHOLOGICAL DISCUSSION

DR. SIDNEY FARBER*: Dr. Burgin has described our findings accurately. The patient did have erythroblastosis fetalis. There was also kernicterus or jaundice of the nuclear masses of the brain. The liver was enlarged two and a half times, the spleen eight times. Moderate enlargement of the liver and more marked enlargement of the spleen are characteristic of erythroblastosis fetalis. In congenital syphilis the liver and spleen are much firmer and much more distorted in archi-

tecture than they were in this case. The enlargement of the liver and of the spleen in erythroblastosis may be explained in great part by the presence of large numbers of immature cells of both the red cell and the white cell series. Similar collections of cells were found in this case in the interstitial tissues of the kidneys, pancreas, lungs, heart and many other organs and structures in the body—a finding characteristic of erythroblastosis. In this disease hematopoietic activity is present to a degree greater than that observed in the normal newborn infant, and in many more locations in the body.

Yellow pigmentation, an indication of kernicterus, was present in the basal ganglia and in a number of other cerebral nuclei all the way down the cord. The pigmentation may vary greatly in intensity. Its exact nature is not clearly proved; it is possible that we are dealing with a number of different pigments in this condition. We were under the impression, until a year ago, that kernicterus was characteristic of erythroblastosis fetalis and that impression may be gained from the literature. Dr. Tague Chisholm and I are studying a group of 26 patients with kernicterus. Only 3 of these patients gave evidence of erythroblastosis. Many of them were premature infants. The correct interpretation of the nature of kernicterus must await further study. It is safe to say that the icterus part of the name has been grossly over-emphasized and may not be important.

DR. J. H. MEANS: Is this a form of Cooley's anemia, or is it a quite distinct disease?

DR. FARBER: Erythroblastosis fetalis is quite a distinct disease. Cooley's anemia occurs almost universally in patients of Mediterranean heredity. It may be observed in early life, but it is rare to find it in marked form in the neonatal period. Erythroblastosis fetalis has been found in patients of almost every race and nationality.

DR. TRACY B. MALLORY: There is very great confusion between the two diseases because of the somewhat similar names that have been given to them. A long, very detailed paper by Micklin† about the hereditary aspects of these diseases unfortunately confuses the two. Cooley's or erythroblastic anemia is quite obviously a recessive type of disease, whereas erythroblastosis fetalis occurs, I believe, as a dominant mutation.

DR. GEORGE W. HOLMES: Is there any treatment for it?

DR. HAROLD L. HIGGINS: Transfusion is the treatment of choice, and often causes a dramatic cure.

DR. MALLORY: In a significant number of the

*Assistant professor of pathology Harvard Medical School pathologist Children's Hospital Boston

†Micklin N. T. Erythroblastosis foetalis. *Am J Dis Child* 53:1245 1267 1937

mild cases the patients are being kept alive now, and they raise a very definite problem for future generations. If Macklin is correct, once the mutation has occurred, it is inherited as a dominant characteristic, so that we must expect in the future many more cases of this disease.

DR. JOHN D. STEWART: What neurological symptoms do you expect from kernicterus?

DR. FARBER: Most of the symptoms are dependent on changes in the basal ganglions.

DR. STEWART: It may be the cause of death, in other words?

DR. FARBER: Patients with kernicterus often suffer from some other unrelated disease, such as pneumonia.

DR. STEWART: What cerebrospinal-fluid changes are characteristic?

DR. FARBER: I should say that the spinal fluid shows nothing remarkable.

CASE 27032

PRESENTATION OF CASE

First Admission. An eighteen-year-old girl entered the hospital with the complaint of abdominal pain and diarrhea.

Eight months before entry she began to have painless diarrhea one to three times daily. The onset of the diarrhea was insidious and unrelated to any change in habits or diet. Previously she had had one bowel movement a day. Her stools were watery or mushy, rarely formed. They contained no blood or pus to her knowledge, and at that time she had no other symptoms. Her physician put her on absolute bed rest for one week and restricted her activities for three more weeks, but this treatment had no effect on the symptoms. The diarrhea continued practically unchanged until one month before entry, when for the first time the patient began to have attacks of cramplike low abdominal pain. The pain usually came on during or immediately after supper, was moderately severe, and lasted two to five minutes. It was localized just below and to the right of the umbilicus, and was sometimes accompanied by a dull ache in the lumbar region posteriorly. The pain did not interfere with her activity and never woke her from sleep. Previous to entry the patient lost about 20 pounds in weight. She never had any nausea, vomiting, hematemesis, melena, jaundice, fever or genitourinary or cardiorespiratory symptoms. The diarrhea continued unchanged up to the time of entry. The past history and family history were noncontributory. For three months her physician had been giving her iron, and for one month liver capsules.

Physical examination revealed a well-developed and well-nourished girl lying quietly in bed in no discomfort. The examination was entirely negative except for an area of deep tenderness without spasm in the right lower quadrant of the abdomen. There seemed to be some increased resistance in that area, but no masses could be made out. Pelvic and rectal examinations were negative. The blood pressure was 104 systolic, 86 diastolic.

The temperature was 98°F., the pulse 100, and the respirations 20.

Examination of the urine was negative. The blood showed a red-cell count of 3,940,000 with 65 per cent hemoglobin, and a white-cell count of 5000 with 70 per cent polymorphonuclears, 26 per cent lymphocytes, 2 per cent eosinophils and 2 per cent basophils. The stools were repeatedly guaiac negative. A Frei test and a 1:1000 tuberculin test were negative. The stomach contents contained 91 units of free acid and 32 units of combined acid after the administration of histamine and alcohol.

X-ray examination of the chest was negative. A barium enema showed no evidence of disease in the colon or cecum. A gastrointestinal x-ray series showed marked narrowing and irregularity of the terminal ileum. The mucosal folds were irregular and partially destroyed, and segments of the bowel showed multiple small irregular filling defects. The involved portion of the bowel was rigid and distinctly palpable. There was no obstruction to the flow of barium, the motor meal having reached the hepatic flexure in six hours. There was some gas in the upper ileum and jejunum, but no evidence of dilatation.

During her stay in the hospital the patient never had more than one stool a day, although they were all mushy. She also had no attacks of pain. Proctoscopy done on the seventh day was negative. She was discharged on the eighteenth day.

Second Admission (fourteen months later). The patient was discharged on a regime of rest with limited activities, a high-vitamin, high-calorie, low-residue diet, and yeast, cod liver oil and ferrous sulfate medication. For several weeks after discharge she had two or three loose bowel movements a day without other symptoms, but after that time she began to have one normal bowel movement daily and was essentially symptom free until three and a half months before re-entry. Occasionally she had a loose bowel movement, but not with any regularity. A gastrointestinal x-ray series six months after discharge showed little or no change from the previous examination. During the six months the patient gained 13 pounds in weight. About three and a half months before

the second admission, however, she again began to lose weight and to have some general malaise. She also had attacks of dull aching pain, which came on just before eating, occurred two or three times a day, were not increased by eating, were localized to the right of the umbilicus, and lasted about fifteen minutes. On occasions the pain would awaken her at night. She had some anorexia and nausea, and often vomited small amounts after meals. Her physician thought that the iron medication was causing the symptoms; following its removal the nausea and vomiting ceased, but the pain continued. The patient also continued to have occasional loose bowel movements. She thought that her general health had been gradually failing. She became more easily fatigued, lacked energy, and lost a total of 20 pounds in weight during the three months before re-entry. She always followed her diet, but for the three months prior to the second admission took no iron, and for the month before re-entry no yeast or cod-liver oil.

Physical examination revealed a well-developed, well-nourished girl who was somewhat pale but not acutely ill. In the right lower quadrant a tubular mass, which was slightly tender on deep pressure, could be palpated. The examination was otherwise negative. The blood pressure was 112 systolic, 60 diastolic.

The temperature was 99°F., the pulse 105, and the respirations 20.

Examination of the urine was negative. The blood showed a red-cell count of 4,000,000 with 70 per cent hemoglobin, and a white-cell count of 8500 with 78 per cent polymorphonuclears. The stools were soft and repeatedly guaiac negative. The corrected sedimentation rate was 0.8 mm. per minute.

A gastrointestinal x-ray series showed a grossly constricted, irregular loop of lower ileum, in which the mucosal pattern was completely destroyed. There was also dilatation of the upper ileum.

An operation was performed on the fifteenth day.

DIFFERENTIAL DIAGNOSIS

DR. JOHN D. STEWART: We are given a diagnostic problem the central feature of which is a protracted, mild, bloodless diarrhea, during the course of which abdominal pain and impairment of the general health and nutrition appeared. It is further to be noted that fever was absent, and that a tender tubular mass was later apparent in the right lower quadrant, where the abdominal pain had been most noticeable. On the basis of the symptomatology one thinks first of affections

of the colon, which produce chronic diarrhea. Chronic ulcerative colitis, a disease of unknown etiology subject to exacerbations and remissions, is a not uncommon cause of diarrhea and gradual deterioration in health. There may be crampy, unlocalized abdominal pain as the diarrhea becomes severe, and gross or occult bleeding is the rule. This diagnosis has been excluded in the present case, however, by the absence of blood in the stools, the negative barium-enema study, and the normal findings on proctoscopic examination. Chronic ulcerative colitis results in destruction of the colonic mucosa, with narrowing of the lumen, rigidity of the wall and loss of haustration. Since the ulcerations commonly appear first in the distal colon, the proctoscopic examination often gives conclusive diagnostic evidence. Tuberculosis of the colon may produce chronic diarrhea of variable severity, as may amebic ulceration of the colon, and into the differential diagnosis also comes lymphopathia venereum, which occasionally results in ulceration and stricture of the rectum or colon. However, disease of the colon has been conclusively excluded in this case by the negative barium enema and proctoscopic examination, and the negative tuberculin test and Frei test are in conformity with this conclusion. Polyposis and carcinoma of the colon may also be regarded as eliminated from the diagnostic possibilities, and the course of the disease seems to be too long and the diarrhea too mild for bacillary dysentery.

It does not come as a surprise to be told that the gastrointestinal x-ray series showed narrowing and irregularity of the terminal ileum, with partial destruction and ulceration of the mucosal folds. Ulcerations of the terminal ileum may produce cramplike central abdominal pain, nausea and vomiting and mild diarrhea. The dull ache in the lumbar region could be due to inflammatory infiltration of the mesentery of the small intestine or to involvement of the posterior parietes.

The question arises whether the ulcerations in the terminal ileum are due to neoplasm, such as lymphoblastoma, cancer or carcinoid, to tuberculosis or to so-called "regional enteritis," the cause of which is as yet unknown. The differentiation of ileal ulceration due to neoplasm from that due to chronic inflammation rests chiefly on the x-ray findings, although the protracted course of the process and the paucity of symptoms of obstruction of the lumen tend to exclude neoplasm. The three gastrointestinal x-ray studies made over a period of fourteen months showed an advancing ulcerating process in a loop of terminal ileum, with destruction of mucosa, narrowing of the lumen and loss of motility. Later, dilatation of the small intestine proximally was

spection of the films made at the third x-ray study of the small intestine shows the so-called "string sign," which consists of a thin stream of unevacuated, opaque medium in a narrowed rigid-walled lumen. I believe that these findings could all be due to tuberculosis, but regional enteritis is the likelier diagnosis. The negative tuberculin test, though of course not conclusive, is evidence against tuberculous enteritis.

The patient was given a careful trial of non-surgical treatment, including rest and high-carbohydrate, high-vitamin low-residue diet. A period of temporary improvement followed, but unfortunately this was not maintained, which not infrequently occurs in the management of this disease. Surgical treatment then became necessary, and probably consisted either of resection of the diseased ileum and mesentery or of a sidetracking ileocolostomy.

The most probable diagnosis seems to be regional ileitis, with secondary malnutrition and partial obstruction of the small intestine.

CLINICAL DIAGNOSIS

Regional ileitis.

DR. STEWART'S DIAGNOSIS

Regional ileitis, with secondary malnutrition and partial obstruction of the small intestine.

ANATOMICAL DIAGNOSIS

Idiopathic regional ileitis.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: As Dr. Stewart has pointed out, the diagnosis, once all the data were in, could hardly have been anything but idiopathic regional ileitis. The important point in the diagnostic work-up of such a patient is to be sure that the roentgenologist's attention is called to the possibility of a small-bowel lesion so that he may make suitable adaptations in technic.

The patient was operated on by Dr. Leland S. McKittrick not simply because she had regional ileitis but because he believed it had resulted in intestinal obstruction of sufficient degree to demand surgical intervention. At operation he found that the ileum, beginning at a point 5 cm. from the ileocecal valve and extending upward for a distance of 20 cm., was thickened and contracted. Its serosa seemed velvety, and the mesentery was considerably thickened. Numerous enlarged lymph nodes, ranging up to 1.5 cm. in diameter, were present in

the corresponding segment of the mesentery. For technical reasons the cecum, as well as the terminal 40 cm. of ileum with the corresponding mesenteries, was resected, and a lateral anastomosis to the ascending colon was performed.

When the specimen was examined in the laboratory the process was found to be even more extensive than had been thought at operation. It extended from the ileocecal valve, which was markedly stenotic, upward for a distance of 40 cm., leaving only 5 cm. of uninvolved bowel at the upper margin of the resection. There were also several small ulcers in the cecum. In the ileum the ulcers were characteristically located over the mesenteric attachment, though the mucosa was inflamed throughout. All layers of the wall were thickened by inflammatory infiltration and scar tissue. A very characteristic feature, also exemplified here, is the thickening and induration of the fat pad at the point of mesenteric attachment. The lymph nodes in the mesentery are usually enlarged, and in this case they were big, wet and soft. Microscopically these cases usually show a nonspecific inflammatory reaction in the mucosa, with polymorphonuclear leukocytes, lymphocytes and large numbers of plasma cells. Usually, but not always, focal collections of epithelioid cells and giant cells in tuberculoid arrangement are present. Caseation is never found, and no tubercle bacilli can ever be demonstrated. The reaction is very similar to that seen in sarcoid. In this patient the lymph nodes were full of such areas, and the resemblance to sarcoid was particularly striking. So far as I know, however, no case of regional ileitis has ever been reported showing any of the well-recognized forms of sarcoid, such as skin lesions, dactylitis, hilar-node involvement, miliary lesions in the lung or uveoparotid fever.

The subsequent course of this patient has also been very typical. Following operation she had no further attacks of pain. The tendency to diarrhea continued, however. At a routine check-up six months later, x-ray examination showed recurrence of the disease in the terminal 15 cm. of the ileum adjacent to the anastomosis. A year later the area of involvement had doubled in length. Subsequent treatment has been medical, with a low-residue, high-vitamin diet, iron and liver, and the patient has been kept fairly comfortable, except for complicating hemorrhoids, though her course has been slowly downhill. No one has shown any enthusiasm for further surgical intervention.

MEDICAL SERVICE CORPORATIONS

ELSEWHERE in this issue of the *Journal* is a copy of the petition and proposed enabling act recently submitted by the Massachusetts Medical Society to the General Court of the Commonwealth of Massachusetts. The Society seeks legislation to permit the formation of a corporation or corporations, nonprofit in character, that will offer a means of meeting the costs of medical care.

In drafting this bill the special committee followed the outline submitted to and approved by the Council in October, 1940, incorporating various suggestions made by the Council at that time. The final form was approved by the Committee on Public Relations.

The guiding principles were as follows: that

subscription be on a voluntary basis; that participation be open to all physicians licensed to practice in Massachusetts; that the Massachusetts Medical Society exercise indirect supervisory control of the corporation or corporations through its approval of the appointment of the majority of the directors; and that the corporation or corporations be under the control of the commissioner of insurance.

That any such plan should be on a voluntary, rather than compulsory, basis is agreed by all.

Whether all licensed physicians should be allowed to participate in the dispensing of medical care has been controversial. In fact a supplementary bill has been filed that is quite similar to that of the Society, the chief exception being a provision for the possible limitation of participating physicians to certain minimum requirements over and above licensure. Although it is acknowledged that every effort should be made to improve the standards of medical care, to try to accomplish this by legislation seems both improper and unwise. The special committee is strongly of the opinion that any state-wide, medical-costs insurance plan sponsored by the Society should include the right of all licensed physicians to participate.

Any such corporation concerned with medical care should obviously be under the direct or indirect control of those who are supplying medical service, namely, the physicians. Hence the provision that a majority of the directors be approved by a well-established and sizable medical society is logical.

It seems wise that such a plan be under the supervisory control of the commissioner of insurance, especially in view of the experience of other states, notably New Jersey. By so doing the corporation better protects itself and its subscribers.

The bill specifically states that it in no way interferes with the activity of any insurance company, any fraternal benefit society or any corporation organized under Chapter 180 of the General Laws. This section clearly refutes any charge that the Society is endeavoring to create a monopoly of such plans.

The bill is submitted as evidence of a sincere effort on the part of the Massachusetts Medical Society to meet the present-day problems of low-income groups in regard to paying for medical care. All members of the Society should become thoroughly familiar with the general principles of the bill, and should explain its purpose to laymen at every opportunity.

GRADUATE EDUCATION FOR INTERNS

IN recent years the internship has been discussed from several points of view, but although the realization has grown that it presents an exceptional educational opportunity, there has been far too little transmission of this thought into action in accordance with a carefully planned procedure. Only recently has the educational value of the internship been estimated so highly that it is regarded as requiring considerable planning as to content and schedule. There is as yet no general agreement about what the intern should accomplish or about the functions that he may reasonably be expected to perform. In some medical schools, a year's internship is required before the degree is conferred; and in some states one year of internship in an approved hospital is a condition for admission to examination as a qualified practitioner. In many states and in most medical schools, however, the internship receives no formal recognition, although it may well include one of the critical periods in the life of the physician. At present nearly every physician who is free to choose spends at least one year in a hospital before he begins the independent practice of medicine.

In the process of transition from the old type of internship with almost no supervision to the ultramodern internship with almost a complete laying out of time for practical work and study, it is extremely interesting to consider the various ways in which this relatively new problem is being approached. It is for this reason, as well as for its intrinsic merit, that the paper by Dr. Nathan Smith, which appears in this issue of the *Journal*,

deserves careful review by the staff members of all hospitals that have interns.

Dr. Smith's plan is to provide an internship that will be a good useful introduction to the general practice in which most physicians will engage. But he considers it also the best foundation for specialism. In this respect his plan differs radically from the procedure adopted by a number of other hospitals, of which the Massachusetts General Hospital is one. On June 1, 1940, a brochure entitled "Graduate Training in Surgery" appeared in which the system recently adopted for surgical interns and residents in that institution is described. In the period devoted to the graduate training in surgery,—about five years and eight months,—opportunity will be given for work in "any laboratory in this country or abroad" under certain conditions, the subject of the study not being stated, and for a "short clinical internship" in "obstetrics or any other clinical field." Thus little time is devoted to fields outside surgery. Another interesting feature of this procedure is that it seems not to pyramid; that is, if the candidate survives the internship, he is in direct line for the residency. This system has problems of its own, but it avoids the rejection of worthy but incompletely trained candidates before the residency is reached simply because there are too many of them for the available positions.

The plan described by Dr. Smith presents another noteworthy feature. The intern is also taught ordinary nursing procedures, so that he may be able to write intelligent nursing prescriptions. This is a significant and much needed reminder that under contemporary conditions the care of the sick requires the co-operation of the medical and the nursing professions.

Each hospital that trains interns and thereby gives them graduate medical education should work out for itself the system best suited to its circumstances, but it should be informed of what others are doing and have accomplished; the experiences of the Morrisania City and Massachusetts General hospitals may well be studied with interest and profit by all.

MEDICAL EPONYM

FRIEDREICH'S ATAXIA

"Ueber degenerative Atrophie der spinalen Hinterstränge [Degenerative Atrophy of the Posterior Spinal Columns]" was described by Professor Nikolaus Friedreich (1825-1882), of Heidelberg, in *Virchow's Archiv für pathologische Anatomie und Physiologie und für klinische Medizin* (26:391-419, 433-459, 1863). He concludes a series of detailed case reports with observations on this condition. A portion of the translation follows:

There is a chronic inflammatory degeneration of the spinal cord that leads to atrophy, and that seems to develop especially in puberty as the result of some hereditary tendency. This is essentially confined to the posterior column, begins in the lumbar portion of the cord, progressing both upward and downward and limited by the elongation of the cord only after involving the origin and roots of the hypoglossal nerves. The affection is characterized clinically by a very gradually developing disturbance of association and harmony of movements, which progresses upward from the lower half of the body, always finally involving the organs of speech. There is complete integrity of the organs of sensation and cerebral function.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

STATED MEETING OF THE COUNCIL

A STATED meeting of the Council will be held in John Ware Hall, Boston Medical Library, 8 Fenway, on Wednesday, February 5, 1941, at 10:30 a.m.

Business:

1. Call to order at 10:30 a.m.
2. Presentation of record of meeting held October 2, 1940, as published in the *New England Journal of Medicine*, for October 31, 1940.
3. Report of Auditing Committee and of Treasurer.
4. Reports of standing and special committees.
5. Appointment of Delegates.
 - (a) To the House of Delegates, American Medical Association, for two years from June 1, 1941.
 - (b) To the annual meetings of the five New England state medical societies in 1941.
 - (c) To the Annual Congress of the American Medical Association on Medical Education and Licensure at the Palmer House, Chicago, February 17 and 18, 1941.
6. Incidental business.

ROBERT N. NYE, *Secretary pro tempore*.

Councillors are asked to sign one of the two attendance books before the meeting. The Cotting Luncheon will be served immediately after the meeting.

COMMITTEE TO STUDY
MEDICAL-COSTS INSURANCE PLANS

A petition for the passage of legislation to permit the formation of a corporation, nonprofit in character, that seeks to pay the medical-care costs of patients was submitted by the Massachusetts Medical Society to the General Court on January 11, 1941. A copy of the proposed act, approved by the Committee on Public Relations follows.

THOMAS H. LANMAN, *Chairman*.

* * *

AN ACT PROVIDING FOR THE FORMATION
OF MEDICAL SERVICE CORPORATIONS

WHEREAS, The deferred operation of this act would tend to defeat its purpose, therefore it is hereby declared to be an emergency law, necessary for the immediate preservation of the public convenience, be it

ENACTED by the Senate and House of Representatives in General Court assembled, and by the authority of the same, as follows:

The General Laws are hereby amended by inserting after chapter one hundred and seventy-six A, as appearing in the Tercentenary Edition, as amended, the following new chapter:

CHAPTER 176B

MEDICAL SERVICE CORPORATIONS

Section 1. In this chapter the following words shall have the following meanings:

"Commissioner," the commissioner of insurance.

"Covered Dependent," a dependent for whose medical care provision is made in a subscription certificate issued by a medical service corporation to a subscriber.

"Dependent," the spouse, child or foster child of a subscriber, or an adult relative dependent upon the subscriber for his or her support.

"Medical Service," the general and special medical services ordinarily provided by registered physicians in accordance with accepted practices in the community where the services are rendered.

"Medical Service Corporation," a corporation organized under the provisions of this chapter for the purpose of establishing and operating a non-profit medical service plan.

"Non-profit Medical Service Plan," a plan operated by a medical service corporation under the provisions of this chapter, whereby the cost of medical service furnished to subscribers and covered dependents is paid by the corporation to participating physicians and to such other physicians as are provided for herein.

"Participating Physician," a registered physician who agrees in writing with a medical service corporation to perform general or special medical service for subscribers and covered dependents at such rates of compensation as shall be determined by its board of directors and to abide by the by-laws, rules and regulations of such corporation.

"Registered Physician," a physician registered to practice medicine in the commonwealth of Massachusetts as provided in section two of chapter one hundred and twelve.

"Subscriber," a person who has subscribed to a non-profit medical service plan and to whom a subscription

certificate has been issued in accordance with the provisions of section six.

Section 2. For the purpose of establishing, maintaining and operating a non-profit medical service plan, any seven or more persons may form a medical service corporation. Such a corporation shall be formed in the manner prescribed in and subject to section nine of chapter one hundred and fifty-five and sections six and eight to twelve inclusive of chapter one hundred and fifty-six, except as follows:

The agreement of association of a corporation having no capital stock may omit the statement of the amount of the capital stock and the par value and number of its shares. The fee to be paid to the state secretary upon the filing of the certificate of condition shall be ten dollars.

Every certificate of organization and every amendment to the articles of organization or by-laws of such a corporation shall have endorsed thereon or attached thereto the consent of the commissioner.

Section 3. The by-laws of a medical service corporation may contain any lawful provisions approved by the commissioner and shall provide that a majority of the directors shall at all times be persons approved in writing by a medical society incorporated in Massachusetts not less than ten years and having not less than two thousand registered physicians as members. The by-laws of such a corporation may define the qualifications of those persons eligible to become subscribers as provided in section five. Any such corporation may adopt such rules and regulations as may be consistent with the provisions of this chapter.

Section 4. Any medical service corporation may enter into contracts with its subscribers and with participating physicians for the rendering of medical service to the subscribers. A contract with a subscriber may provide for the medical care of any dependents of the subscriber named therein. The form of subscription certificate and of agreement with participating physicians, the rates charged by such corporation to the subscribers and the rates at which participating physicians are compensated for their services to the subscribers or to covered dependents, and the acquisition costs in connection with the solicitation of subscribers shall at all times be subject to the written approval of the commissioner.

Section 5. Any person residing in the commonwealth shall have the right to become a subscriber of a medical service corporation if his qualifications meet those specified in the by-laws of such corporation, provided that such a corporation may, in its discretion, refuse to issue a subscription certificate to, or upon due notice cancel the subscription certificate of, any person if such person has made any fraudulent claim or representation to the corporation or to a participating physician, or has been guilty of uncooperative or unethical dealings with the corporation, or has failed to pay dues and assessments seasonably and promptly or for any other cause which may be approved by the commissioner.

Section 6. A subscription certificate shall be issued to each subscriber of a medical service corporation. No subscription certificate shall be issued unless the commissioner shall have approved in writing the form of certificate nor unless it contains in substance the following provisions:

(a) A statement of the medical service to be paid for by the corporation, and if any medical service is excepted, a statement of such exception.

(b) A statement of the duration of the agreement and of the terms and conditions upon which it may be

extended, renewed, revised, canceled or otherwise terminated.

(c) A statement of the period of grace which will be allowed for making any payment due from the subscriber under the contract, which in any event shall not be less than thirty days.

A subscription certificate may incorporate by reference the by-laws, rules and regulations of a medical service corporation provided a copy of the said by-laws, rules and regulations is available upon request to any subscriber.

Section 7. Every registered physician shall have the right on complying with such regulations as the corporation may make to enter into a written agreement with a medical service corporation doing business in the city or town where the said physician resides or has his usual place of business to perform general or special medical service. This chapter shall not change the normal relations between physician and patient. No restriction shall be placed by any such corporation upon its participating physicians as to methods of diagnosis or of treatment. No officer, agent or employee of a medical service corporation shall influence or attempt to influence a subscriber or a covered dependent in his choice of a participating physician. A subscriber or a covered dependent, subject to the by-laws, rules and regulations of a medical service corporation and the terms and provisions of his subscription certificate, shall be entitled to the benefits of this chapter upon receiving medical service from any participating physician or, in the discretion of the corporation, upon receiving medical service from any non-participating physician in an emergency or when outside the commonwealth. A corporation may terminate its agreement with any participating physician at any time (a) for failure to comply with the reasonable rules and regulations of such corporation, including without limitation such rules as may be adopted governing the keeping of accounts, records, and statistics, the making of reports and proof of services rendered, or (b) for presenting any fraudulent, unreasonable, or improper claim for payment, or compensation.

Section 8. Every medical service corporation shall annually, on or before the first day of March, file in the office of the commissioner a statement, verified by at least two of the principal officers of said corporation, showing its condition as of the thirty-first day of December next preceding. Such statement shall be in such form and shall contain such matters as the commissioner shall prescribe. A corporation neglecting to file its annual statement within the term herein specified shall forfeit one hundred dollars for each day during which such neglect continues, and upon notice by the commissioner to that effect, its authority to do business shall cease while such default continues.

Section 9. The commissioner, or any deputy examiner or any other person designated by the commissioner, shall, at least once in three years, and whenever the commissioner deems it prudent, visit any medical service corporation and examine into its affairs. The commissioner shall have free access to all of the books, records and papers of the corporation, and may summon and examine under oath its officers, agents, employees and other persons in relation to its affairs and condition. The commissioner shall require every such corporation to keep its books, records, accounts and vouchers in such manner that he or his authorized representatives may readily verify its annual statement and determine whether the corporation has complied with the law.

Section 10 The funds of a medical service corporation shall be invested only in such securities as are permitted by chapter one hundred and seventy five for the investment of the capital of insurance companies, or it may deposit the whole or any portion of its funds in any savings bank or savings department of a trust company or organized under the laws of the commonwealth or a national banking association. It shall have the right to acquire and own real estate to be occupied by itself in the transaction of its business. The commissioner may require any such corporation after the first full calendar year of doing business to accumulate and maintain a special contingent surplus, over and above its reserves and liabilities in such amount as the commissioner may deem proper.

Section 11 Unless each such payment is first authorized by a vote of its board of directors, no medical service corporation shall pay any salary, compensation or emolument to any officer, trustee or director thereof, or any salary, compensation or emolument to any person amounting in any year to more than five thousand dollars. No such corporation shall make any agreement with any of its officers, trustees or employees whereby it agrees that for any services rendered or to be rendered to it, they shall receive any salary, compensation or emolument for a period of more than three years from the date of such agreement.

Section 12 Any dispute or controversy arising between a medical service corporation and any participating physician, or any subscriber, or any person whose subscription certificate has been canceled or to whom such corporation has refused to issue a certificate as provided in section six may within thirty days after such dispute or controversy arises be submitted by any person aggrieved to a board serving in the division of insurance and consisting of the commissioner or a person designated by him the chairman of the board of registration in medicine or a person designated by him, and the attorney general or a person designated by him, for its decision with respect thereto. All decisions and orders of the board or of the commissioner made under any provision of this chapter may be revised as law and equity may require upon a petition in equity filed, within ten days after the promulgation of such decision or order in the superior court within and for the county of Suffolk by any party aggrieved by such decision or order.

Section 13 If the commissioner is satisfied as to any medical service corporation, that (1) it has failed to comply with the provisions of its charter, or (2) it is being operated for profit, or (3) it is fraudulently conducted, or (4) its condition is such as to render its further transaction of business hazardous to the public or to its subscribers, or (5) its officers and agents have refused to submit to an examination under section nine, or (6) it has exceeded its powers, or (7) it has violated any provision of law, or (8) it has compromised, or is attempting to compromise, with its creditors on the ground that it is financially unable to pay its claims in full or (9) it is insolvent he may apply to the superior court within and for the county of Suffolk for an injunction restraining it from further proceeding with its business. The court may forthwith issue a temporary injunction restraining the transaction of any business, and it may, after a full hearing make the injunction permanent, and appoint one or more receivers to take possession of the books, papers, moneys and other assets of the corporation, settle its affairs and distribute its funds to those entitled thereto, subject to such rules and orders as the court may prescribe.

Section 14 Every medical service corporation is hereby

declared to be a charitable corporation. No such corporation shall be liable for injuries resulting from negligence or malpractice on the part of any participating physician or of any of its employees. Every such corporation shall be exempt from all provisions of the insurance laws of the commonwealth, except as otherwise provided in this chapter. The property of every such corporation shall be exempt from all state and local taxes and such corporation shall not be subject to any tax or excise on or with respect to its corporate franchise or with respect to the doing of business.

Section 15 It shall be unlawful for any person, firm, corporation or association, except a medical service corporation, to establish, maintain or operate a non-profit medical service plan, provided, however, that this chapter shall not render unlawful or affect any operation or activity of any company organized or to be organized under the provisions of chapter one hundred and seventy five, of any society or fraternal benefit society organized or to be organized under the provisions of chapter one hundred and seventy six, of any non-profit hospital service corporation organized or to be organized under the provisions of chapter one hundred and seventy six A, or of any corporation organized or to be organized under chapter one hundred and eighty, the existence, purposes, activities and operations of which were lawful or would have been lawful prior to the enactment of this chapter.

Section 16 The provisions of this chapter may be enforced by a bill in equity brought in the superior court within and for the county of Suffolk or in the county where any defendant resides or has his or its usual place of business to be brought by the commissioner, the attorney general, or any district attorney.

COMMITTEE TO CONSIDER NEW OFFICERS AND BY LAWS

Following the Council meeting of October 2, 1940, a committee was appointed by the president of the Massachusetts Medical Society to study the desirability of establishing the offices of president elect and full time or executive secretary and to suggest the necessary changes in the by laws required to create these positions. The committee believes that these two new positions are desirable and has consequently formulated the changes in the by laws necessary for the creation of these offices.

In respect to the second part of its duties, that is, to study the propriety of altering the constitution and by laws in such a way that they would conform to those of other state medical societies, the committee reports that any attempt in the nature of redistricting involves too great a change in policy for a committee of this sort, which is probably not sufficiently representative, to act upon.

The committee has seen no need of altering the nomenclature of the governing body, the Council, or its method of election. It does recommend the creation of an Executive Committee of the Council—a smaller body, selected in such a way

as fairly to represent, geographically and numerically, the fellows of the Massachusetts Medical Society.

There is also submitted a table to explain the units represented by the elected members of the Executive Committee. (The ease of geographic division is apparent if one refers to the map of the district societies in the *Directory*.)

The changes in the by-laws necessitated by the creation of the offices of president-elect and executive secretary and the creation of an Executive Committee of the Council follow.

CHAPTER III

DISTRICT SOCIETIES

Section 5. (Additional.)

The councilors of each district society shall meet as soon as possible after the annual meeting of the district society in 1941 and elect two or more of their number to serve as candidates for the Executive Committee of the Council in accordance with chapter IV, section 10; and thereafter in a similar manner they shall choose new candidates from time to time.

Section 7. (Additional.)

The secretary of each district society as soon as possible after the annual meeting of the district society in 1941 shall call together its councilors for the purpose of selecting the candidates for the Executive Committee of the Council and shall send the names of those chosen to the Secretary of the general Society. He shall see that new candidates are chosen in a similar manner to fill vacancies as they occur, in accordance with chapter IV, section 10.

CHAPTER IV

THE COUNCIL

Section 1. The Council shall consist of councilors chosen by the district societies, and the President, ex-presidents, President-Elect, Vice-President, vice-presidents *ex officio*, Secretary and Treasurer of the general Society, secretaries of the district societies, and the chairman of each standing committee.

Section 3. The Council at its annual meeting, on nomination by the Nominating Committee and/or from the floor, shall elect by ballot officers of the Society as follows: President-Elect, who shall serve as President-Elect until the annual meeting of the Society next ensuing after his election and shall become President on his installation in the course of that meeting, serving thereafter as President until the next following annual meeting and the installation of his successor; a Vice-President, Secretary and Treasurer, all of whom shall assume the duties of office at the close of the annual meeting of the Society and shall hold office until their successors have been duly elected; except only that at the annual meeting of the Society in 1941 there shall be nominated and elected a President to

serve for that year. Councilors only shall be eligible to the offices above named. Upon nomination by the Nominating Committee, it shall elect by ballot a fellow to deliver an oration at the annual meeting of the Society the following year.

Upon nomination by the Nominating Committee, it shall elect by ballot members of the Executive Committee representing, respectively, the various units of district societies in accordance with section 10 of this chapter.

Section 10. The Executive Committee shall consist of the President, President-Elect, Vice-President, Treasurer and Secretary *ex officio*, the chairmen of the following standing committees, namely, Ethics and Discipline, Financial Planning and Budget, Membership, Publications and State and National Legislation, and those members elected by the Council.

The elected members, all of whom shall be councilors, shall be chosen, respectively, from geographical units of the Society so arranged that each member of the Executive Committee shall represent at least five hundred fellows of the Society as of January 1, 1941; except that if the number of fellows in any unit shall thereafter fall below five hundred, that unit shall still be entitled to its member, unless the Council orders otherwise.

These members shall be nominated and elected in the following manner:

(a) The councilors of each district society shall meet as soon as possible after its annual meeting in 1941 and in a similar manner at stated intervals thereafter, as specified below, to choose two of their number for presentation to the Nominating Committee; except that the councilors of any district society which alone represents one unit shall choose four nominees, and except that the councilors of any district society having more than five hundred fellows shall choose two additional nominees for each additional five hundred fellows or major fraction thereof.

(b) From the list of nominees representing each unit, the Nominating Committee shall choose, for election at the next annual meeting of the Council, at least twice the number of names eligible for election from that unit.

(c) From the list of councilors offered by the Nominating Committee, the Council at its annual meeting shall elect by ballot, to represent each unit of district societies, one or more members to serve on the Executive Committee, according to the following plan, which may be altered by the Council at its annual meeting from time to time:

From Berkshire, Franklin, Hampden and Hampshire, designated as the Western Unit, one member.

From Worcester and Worcester North, designated as the Worcester Unit, one member.

From Middlesex North, Middlesex South and Middlesex East, designated as the Middlesex Unit, two members.

From Essex North and Essex South, designated as the Essex Unit, one member.

From Suffolk, designated as the Suffolk Unit, one member.

From Norfolk and Norfolk South, designated as the Norfolk Unit, two members.

From Plymouth, Bristol North, Bristol South and Barnstable, designated as the Cape Unit, one member.

(d) The members of the Executive Committee shall serve for three years and shall not be eligible for reelection

before the expiration of three years following the conclusion of their terms of office, except that in 1941 three members shall be selected by lot to serve one year, three members shall be selected by lot to serve two years and three members shall be selected by lot to serve three years. Thereafter three members shall be elected every year to succeed in office those whose terms are about to expire.

Basis for Election of Members of Executive Committee of the Council

and shall be nominated by the councilors of the various district societies concerned, as already described in subsections a, b and c of this section, unless the Council otherwise directs.

The Executive Committee shall meet at the call of the President at least once in each interval between Council meetings and may meet more often at the pleasure of the President. It shall assist the President in preparing for the consideration of the Council matters calling for action by the Council at its next meeting. It shall authorize action when circumstances require it, subject to the approval of the Council. It shall perform such other duties as the Council may require.

The consent of the Executive Committee shall be required to confirm the appointment, upon nomination by the President, of the Executive Secretary of the Society.

Upon request, members of the Executive Committee shall be paid the amount of their traveling expenses from the funds of the Society.

CHAPTER V

CENSORS AND SUPERVISORS

Section 1 The supervisors, representing the censors of the several district societies, shall constitute a board, which

shall meet annually on the day appointed for the annual meeting of the Council. The board shall elect a chairman, who shall have power to call special meetings. Five supervisors shall constitute a quorum. The secretary or executive secretary of the general Society shall act as secretary of the board. He shall keep a permanent record of the proceedings of the board, and shall provide, at the expense of the Society, papers and forms necessary for conducting examinations of applicants for fellowship. The board at its annual meeting shall adopt a uniform plan for the examination of applicants. The supervisors shall be paid the amount of their traveling expenses from the funds of the Society.

CHAPTER VI

OFFICERS

Section 1 (Additional)

He shall call at least one meeting of the Executive Committee of the Council between Council meetings and may call more meetings if he so desires.

Section 2 In the absence of the President, the Vice President shall perform all the duties of the President, and in the absence of both, the senior Vice President *ex officio* in point of membership shall perform the duties of the President.

Section 3 The President Elect shall assist the President in the performance of his duties in such a manner as the President may direct and in so doing shall be considered to represent the President.

In the absence of the President Elect, the Council, at its next annual meeting, shall, upon nomination by the Nominating Committee and/or from the floor, elect a President.

Section 4 The Secretary may assign to the Executive Secretary any or all of the duties now to be enumerated, except as specified below.

The Secretary shall attend all meetings of the Society and of the Council, and shall record their respective proceedings in separate record books, and this duty he may not assign.

He shall cause to be engrossed and shall sign the diplomas of new fellows if satisfied that they have met the requirements of sections 1 and 2 of chapter I, and shall issue all diplomas and certificates of fellowship. He shall notify individual fellows, in appropriate instances, of votes by the Council granting permission, as the case may be, to retire, to resign, to change district membership, to have dues remitted, or of votes depriving them of the privileges of fellowship, and these duties he may not assign.

He shall act *ex officio* as secretary of all boards of trial, and this duty he may not assign.

He shall have custody of the seal of the Society and of all books, papers, manuscripts, prints and paintings belonging to the Society, except such as are in charge of the Treasurer, and this duty he may not assign.

He shall act *ex officio* as secretary of the Board of Supervisors and of the Committee on Publications and the Committee on Ethics and Discipline, and shall keep the records of each in a separate volume. He shall have custody of all records as thus kept.

He shall issue notices of the meetings of the Council one month before the annual meeting of the Society. He shall issue to every fellow a program which shall contain (a) notification of the time and place of the annual meeting, (b) notification of the stated meetings of the Council for the year, and the meetings of the boards of censors, (c) information concerning the payment of assessments, and the distribution of publications.

He shall record the *Proceedings of the Council and of the Society*. He shall keep a complete list of the fellows of the Society, with their addresses so far as known. He shall transfer fellows from one district to another under the terms of chapter III, section 2, and shall report to the Society at its annual meeting the changes in membership of the Society during the year.

He shall conduct the official correspondence of the Society, and shall notify officers, delegates, and members of the committees of the general Society of their appointments and of their duties.

Under the direction of the Committee on Publications he shall issue at such intervals as may be determined by the Council a directory of officers and fellows of the Society, which shall be furnished upon request to fellows who are not in arrears.

He shall perform such other duties as the Society or the Council may require.

Section 5. The Executive Secretary shall be chosen by the Executive Committee of the Council upon nomination by the President. He shall hold office for one year or until his successor has been duly elected.

He shall perform such duties as are assigned to him in section 4 of this chapter and by the Executive Committee. In general, he shall assist the officers of the Society and such standing and other committees as may request his services, and his preoccupation shall be the service of the Society.

He shall attend all meetings of the Council and, on request, attend the meetings of the Executive Committee of the Council, but shall not vote in either.

The Executive Secretary need not be a fellow of the Society and nothing in this section shall forbid the choice of a woman for the office.

COMMITTEE ON MEDICAL EDUCATION AND MEDICAL DIPLOMAS

The Committee on Medical Education and Medical Diplomas has been directed by the Council to submit changes in the by-laws relative to the admission to the Society of graduates of medical schools not on the list recognized by the Council. At the next meeting of the Council the committee will submit proposed changes in the by-laws designed to accomplish the following:

1. To change its name to the Committee on Medical Education.
2. To change the date of the fall censors' examination from the first Thursday in November to the first Thursday in December.
3. To collect an examination fee of three dollars from each applicant examined by the censors.
4. To disqualify an applicant failing two examinations from again applying until three years have passed.
5. To set definite dates for filing applications, publication of names in the *Journal* and so forth.
6. To institute sponsorship by a fellow of the Society for each applicant who is a graduate of an unrecognized school.
7. To institute a local board of membership for each district society composed of the president, secretary and supervising Censor, who shall have the responsibility of interviewing each applicant who is a graduate of an unrecognized school, collecting information about him, and submitting recommendations to the Committee on Medical Education as to whether or not

he should be allowed to appear before the censors. The Committee on Membership shall render the final decision, as at present.

8. To give power to the Committee to change the list of medical schools recognized by the Council whenever such action appears necessary to the Committee.

With the approval of the Committee on Ethics and Discipline there will also be submitted proposed changes in the by-laws designed to accomplish the following:

9. To have an investigation by the local board of membership of every former fellow who seeks readmission to the Society, the recommendations to be submitted to the Committee on Membership, which shall report to the Council. When a resignation has been requested by the Committee on Ethics and Discipline, or where deprivation has occurred for a reason other than non-payment of dues, the board shall consult with the Committee on Ethics and Discipline. No applicant for readmission to the Society shall appear before the board of censors.

JOHN P. MONKS, *Chairman*.

COMMITTEE ON MEMBERSHIP

At the February meeting of the Council a recommendation, to provide for a remission of dues of fellows who are called to full-time service in the United States Army, Navy or Public Health Service, will be presented:

Fellows of the Society who are called to full-time service in the United States Army, Navy or Public Health Service during the present emergency and whose livelihood is thereby impaired may, on written application to the Treasurer stating their situation, have their dues remitted for the year of service. A period of full-time service greater than six months shall give the privilege of a year's remission of dues. The *New England Journal of Medicine* will only be sent to such members on payment of an annual fee of four dollars (\$4.00). The President of the Society shall determine the end of the present emergency.

G. COLKET CANER, *Chairman*.

PREGNANCY COMPLICATED BY CARDIAC DECOMPENSATION AND RESULTING IN DEATH

Mrs. M. P., a twenty-three-year-old primipara, was referred by her family doctor on January 8, 1924, when she was approximately four months pregnant.

The family history was essentially noncontributory. The patient had rheumatic fever at the age

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

of eight years and was kept in bed for six weeks. There was no history of any other disease. A tonsillectomy was performed when the patient was twelve years old. Catamenia began at thirteen, were regular with a twenty-eight-day cycle and lasted four days. The last period began on September 15, 1923, making the expected date of confinement June 22.

Physical examination on January 8 revealed a well developed and well nourished young woman. The weight was 128 pounds. The lungs were clear and resonant; there were no rales. The heart showed definite evidence of mitral stenosis. The blood pressure was 112 systolic, 60 diastolic. The abdomen was negative except for a uterus that was enlarged to a size consistent with the period of amenorrhea. Vaginal examination revealed the cervix to be soft.

On January 29 the weight was 132 pounds. The patient was seen by a medical consultant after she disclosed that she had had some precordial distress and had coughed up blood on two occasions. The consultant's note read as follows:

The patient has a poor heart muscle. The blood pressure is 100/60, the pulse rate 120. The apex impulse is in the 5th intercostal space, 10 cm to the left of the mid-sternal line, the dullness on the right extends 3 cm from the midline, there is slightly increased dullness upward. The apex impulse is light and tapping, and there is some soreness of chest. There is a presystolic thrill, the heart action is regular. At the apex, the first sound is sharp, there are presystolic and systolic murmurs. The pulmonary and aortic second sounds are sharp and clear. There is a question of a few crackles in the right base. Diagnosis: mitral stenosis.

Following this visit the patient was kept in bed for ten days.

On March 19 she complained that she had been having considerable epigastric distress, and she was seen by another medical consultant. At this time she was in the hospital because of discomfort and for the purpose of rest. The consultant concurred in the diagnosis of mitral stenosis and advised that she lead a very quiet life; he also suggested that she be delivered by cesarean section.

On May 1 the patient had an attack of decompensation in the middle of the night. She complained of great difficulty in breathing, and vomited. The pulse was 120. She was advised to stay in bed from then until delivery.

On May 15 she had a slight cold, but her pulse remained about 90 and her condition seemed satisfactory. She was seen at home on May 20, at which time the blood pressure was 118 systolic, 60 diastolic and the pulse 90.

One week later, when the patient was approximately thirty six weeks pregnant, the heart again

became decompensated. She vomited blood and coughed a great deal. The pulse was over 100, and she was pale. She was taken immediately to the hospital, where her condition became steadily worse. She started in labor, and died undelivered on May 28.

Comment. In 1924 the treatment of pregnancy complicated by cardiac disease was little understood, and the complication not particularly well handled. In this case the mitral stenosis dated back to the rheumatic fever and in retrospect the patient never should have become pregnant. When she was first seen by the family physician, the question of therapeutic abortion should have been entertained. When the patient was first seen by the obstetrician at about four months, the problem appeared very grave, but because of the scruples of the family, it was decided to allow the pregnancy to continue.

During her pregnancy there were several attacks of decompensation. The patient was hospitalized once, and was in bed at home a good part of the last months of her pregnancy. In spite of this, decompensation occurred, followed by labor and death. Today, therapeutic abortion and sterilization would be advised very strongly as soon as the patient was seen. Electrocardiograms would be taken. If abortion were refused, such a patient should be hospitalized practically all the time.

It is now believed that in such cases the peak of the load becomes less after the thirty-sixth week, and that many cases go on to spontaneous delivery. There is still a question whether patients as sick as this one should not be delivered by cesarean section under spinal or local anesthesia as soon as viability is established, or at the first signs of cardiac failure.

MEDICAL POSTGRADUATE EXTENSION COURSES

The following sessions, given by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, have been arranged for the week beginning January 19

MIDDLESEX EAST

Tuesday, January 21, at 4 15 p.m., at the Melrose Hospital, Melrose. Chemotherapy in the Treatment of Gonococcal Infection. Instructor Sylvester B. Kelley. Walter H. Flanders, *Chairman*.

MIDDLESEX SOUTH

Tuesday, January 21, at 4 00 p.m., at the Cambridge Hospital, Mt. Auburn Street, Cambridge. Technique and Treatment of Primary, Secondary and Tertiary Syphilis. Instructor Rudolph Jacoby. Dudley Merrill, *Chairman*.

NORFOLK

Thursday, January 23, at 8:30 p.m., at the Norwood Hospital, Norwood. Diagnosis and Treatment of Minor Lesions of Rectum and Anus. Instructor: E. Parker Hayden. Hugo B. C. Riemer, *Chairman*.

NORFOLK SOUTH

Monday, January 20, at 8:30 p.m., at the Quincy City Hospital, Quincy. Obstetric Infections: Diagnosis and treatment. Instructor: John Rock. David L. Belding, *Chairman*.

SUFFOLK

Thursday, January 23, at 4:30 p.m., in John Ware Hall, Boston Medical Library. Pediatric Case Discussions. Instructor: Edwin H. Place. Reginald Fitz, *Chairman*.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATHS

HUSE—ERNEST L. HUSE, M.D., aged sixty, died at Meriden on December 20, 1940. He was known to many as one of the last of the so-called "country doctors."

Dr. Huse graduated from Dartmouth Medical School in 1907. A former president of the Sullivan County Medical Association, he had practiced in Meriden for thirty-one years.

Survivors are his wife, Mrs. Helen Huse, and two sons, E. Leslie, of Allenhurst, New Jersey, and Raymond A., of Hackensack, New Jersey.

MORRILL—SIBLEY G. MORRILL, M.D., of Concord, died Saturday, December 28, 1940, after a long illness. He was born in Concord in 1873, the son of Luther Sullivan and Mary Agnes (Gage) Morrill; he was the grandson of Dr. Charles P. Gage, who began a Concord practice in 1838. Dr. Morrill graduated from the Harvard Medical School in 1898. He had been president of the staff at Margaret Pillsbury General Hospital, consultant at the New Hampshire Memorial Hospital and the Pembroke Sanatorium and a member of the state and city boards of health.

Dr. Morrill was a fellow of the American Medical Association and a member of the New Hampshire Medical Society and the Center District Society.

He married Georgia Sherman in 1905, and after her death married Anna Wenzell. Two sons, Sibley S. Morrill, of San Francisco, and Roger S. Morrill, of Concord, survive him.

MISCELLANY

TUBERCULOSIS AND MILITARY SERVICE

Sixteen and a half million men have registered for military service. Almost one million of them have thus far been selected. According to news reports, the men will be subjected to a hardening process to the point where they will be able to march thirty miles per day bearing full equipment. It is highly important that among them there shall be none who, because of a tuberculous focus, will crack under the strain. So that costly lessons, learned during World War I may not go unheeded, Spillman in a recent article (*The value of radiography in detecting tuberculosis in recruits, J. A. M. A. 115:1371-1378, 1940*) summarizes the methods employed to discover tuberculosis, calculates the enormous cost of service-acquired tuberculosis and discusses what should be done to safeguard the

nation's manpower and financial resources against the enemy that bores from within.

World War I is twenty-two years behind us, yet the federal government pays in compensation for tuberculosis that originated in service about \$3,000,000 each month. Analysis of voluminous and complicated federal reports dealing with service-acquired tuberculosis yields the following approximate figures:

Cost of vocational training.....	\$129,000,000
Insurance	130,000,000
Compensation	600,000,000
Hospital care	100,000,000
	<hr/>
	\$959,000,000

The total number of men compensated for tuberculosis in 1922 (it is not feasible, from the annual reports, to run the figures back past 1922) was 36,600. In 1939, the total number was 55,634, including 1947 deaths for that year.

The expense of taking a man who has tuberculosis into the service cannot be accurately calculated because of many factors that are still unknown and costs that are not apparent, but the author estimates that the figure would be somewhere around \$10,000 per man to date, certainly not less than \$7500, to which should be added at least \$50 a month for the rest of the man's life, and compensation for his dependents after death.

Study of army procedure during World War I leads to the conclusion that the methods employed for the detection of tuberculosis were inadequate. This does not detract from the stature of that distinguished army surgeon, Colonel George E. Bushnell, the adviser to the Surgeon General on all matters pertaining to tuberculosis. It was the consensus of experts in 1917 that adult exogenous infection with tuberculosis is rare, that infection in childhood is well-nigh universal and that every infection confers an immunity to anything short of massive doses of tubercle bacilli in later life. By the same token, adult tuberculosis was held to result from a reactivation of the antecedent infection. It was thought that for every soldier who had *incurred* tuberculosis as a result of military service, ten others had *brought the disease with them* into the army. Present-day experience does not uphold this belief—to cite at random just one of numerous communications. Diehl and Myers proved the development of six cases of tuberculosis in one college fraternity a year after one of its members was found to have a positive sputum, and the development of tuberculosis in a girl several years after her sorority roommate was found to have tuberculosis.

The problem at hand is this: How can the recruit who already has active tuberculosis be recognized, so that he may be rejected for the protection of himself and others? Colonel Bushnell trained a large number of highly competent diagnosticians, to whom he imparted the significance of the post-tussal moist rale and the technic of eliciting it. The patient is instructed to cough gently at the end of deep expiration. When he inhales after the cough, the rale is heard. The presence of persistent moist rales was the criterion for determining the existence of tuberculosis. Several prominent physicians and radiologists tried to induce the Surgeon General to make the radiograph the decisive factor in the diagnosis of pulmonary tuberculosis. The practical difficulties in the way of the adoption of the radiograph were, however, insuperable, according to Colonel Bushnell, in which conviction he was supported by a special committee of the Council of National Defense that investigated the question. Among the difficulties were the enormous cost of photographing,

the impossibility of obtaining a sufficient number of plates (made of glass and most of it imported from Belgium) and the lack of trained radiologists

Draft boards set up in every community added to the difficulty. These boards included local physicians who were supposed to reject draftees with disqualifying defects. Although most draft boards functioned honestly and intelligently, there is evidence in official publications that, far from weeding out the manifestly tuberculous trainees, some boards actually concentrated tuberculosis at some of the camps, thinking that the men would benefit by change of climate and by army life. In the re-examination of 19,827 men at Camp Kerny, for example, 833 cases of tuberculosis (4.3 per cent) were discovered.

With this background, what should our procedure be in the present situation? Of the available methods for the mass diagnosis of tuberculosis among recruits, physical examination and radiography need to be considered on a basis of relative merits. Evidence of the inadequacy of physical examination to detect tuberculosis is overwhelming. The last word so far as the army was concerned in 1917 was that the only trustworthy sign of activity of apical tuberculosis is the presence of persistent moist rales. In the light of present day knowledge this sign is conclusive in only about 12.5 per cent. In spite of the acknowledged skill of the army examiners of 1917, only about one eighth of the actually existent, clinically significant tuberculosis was detected.

The radiograph should be the criterion in weeding out tuberculosis in today's mobilization. In what form? Fluorography gives no record and is highly subjective. As demonstrated by the experience of a large life-insurance company, fluorography in skillful hands may serve as an alternative to a prohibitively expensive routine of roentgenography, but even this company has, since 1936, been making routine roentgenograms of the chest of every applicant for employment.

The paper roentgenogram is speedy and convenient and cheaper than celluloid. Radiologists as a whole do not favor the paper radiogram, whereas tuberculosis workers are enthusiastic over it. If celluloid films were available on rolls like the paper rolls, they would undoubtedly be preferred. Paper roentgenograms are vastly preferred to no roentgenograms, but celluloid would be preferred if the author were given a choice.

Photography of the fluoroscopic screen is another possibility. But if this method, known as fluorography, is no more than 90 per cent efficient as compared with the standard celluloid roentgenogram, as Dr Spillman believes, the 10 per cent shortage in diagnosis would cost a great deal of money in compensation later. Fluorography is today a highly promising method but awaits further improvements before it can compete with celluloid roentgenograms.

For radiography there are many kinds of apparatus varying in price and capacity. What is most important, however, is the skill and knowledge of the operator.

The author's final conclusion is

A normal chest roentgenogram should be the criterion of acceptance in a future mobilization including the proposed draft for training, and it should be made and reported before the recruit has spent a night away from his own roof to obviate a repetition of the claims for aggravation of pre-existing tuberculosis which occurred during and after the World War.

Reprinted from *Tuberculosis Abstracts* January, 1941

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR NOVEMBER, 1940

DISEASE	NOVEMBER 1940	NOVEMBER 1939	FIVE YEAR AVERAGE*
Anterior poliomyelitis	4	7	14
Chicken pox	1269	947	908

*Based on figures for preceding five years

RARE DISEASES

Actinomycosis was reported from Brockton, 1, total, 1.
Anterior poliomyelitis was reported from Ashland, 1, Greenfield, 1, Hadley, 1, Worcester, 1, total, 4.
Diphtheria was reported from Chelsea, 2, Fall River, 5, Foxboro, 1, Sturbridge, 1, Wellesley, 2, Worcester, 1, total, 12.
Dysentery, amebic, was reported from Bridgewater, 1, Somerville, 1, total, 2.
Dysentery, bacillary, was reported from Boston, 1, Cambridge, 8, Everett, 1, Lowell, 2, total, 12.
Infectious encephalitis was reported from Palmer, 1, Springfield, 1, total, 2.
Malaria was reported from Cambridge, 2, total, 2.
Meningococcus meningitis was reported from Gloucester, 1, Lowell, 1, Malden, 1, Medford, 1, Methuen, 1, Milford, 1, Quincy, 1, Springfield, 1, total, 8.
Paratyphoid B fever was reported from Brockton, 1, Fall River, 1, Wellesley, 1, total, 3.
Pellagra was reported from Belmont, 1, total, 1.
Septic sore throat was reported from Boston, 5, Cambridge, 2, Lynn, 1, New Bedford, 1, Quincy, 1, Somerville, 1, Wrentham, 1, total, 12.
Tetanus was reported from Chelsea, 1, total, 1.
Trachoma was reported from New Bedford, 1, total, 1.
Trichinosis was reported from Winchester, 8, total, 8.
Typhoid fever was reported from Boston, 2, Cambridge, 1, Somerville, 1, Woburn, 1, total, 5.
Undulant fever was reported from Barre, 1, Dartmouth, 1, Lynnfield, 1, Plymouth, 1, total, 4.

Measles, mumps, meningococcus meningitis, lobar pneumonia and whooping cough were reported above the five year averages.

Pulmonary tuberculosis showed record low incidence. The incidence of undulant fever was not remarkable. Scarlet fever, diphtheria, German measles and anterior poliomyelitis were reported below the five year averages. Tuberculosis (other forms) was reported at a record low figure.

Diseases of the typhoid-paratyphoid group showed low incidence.

Dog bite was reported at a record high figure for the fourth consecutive month. Animal rabies was reported from Halifax, Hanson, Worcester, Spencer and Leicester.

CORRESPONDENCE

REVOCATION OF REGISTRATION

To the Editor: At the meeting of the Board of Registration in Medicine, held December 19, 1940, the Board canceled the registration as a practitioner of medicine in this Commonwealth and revoked the certificate of registration of Dr. Michael Litvich, 114 Shirley Avenue, Revere, Massachusetts, because of deceit in connection with an automobile accident case.

STEPHEN RUSHMORE, M.D., *Secretary*,
Board of Registration in Medicine.

State House,
Boston.

NOTICES

ANNOUNCEMENTS

G. MARSHALL CRAWFORD, M.D., announces the removal of his office from 416 Marlboro Street, Boston, to 1101 Beacon Street, Brookline.

JOHN C. TATE, M.D., announces the removal of his office from the Westfield State Sanatorium, Westfield, to 20 Maple Street, Springfield.

BOSTON DOCTORS' SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will rehearse under Alexander Thiede, formerly concertmaster of the Cleveland Symphony Orchestra, every Thursday at 8:30 p.m. Those interested in becoming members should com-

municate with Dr. Julius Loman, Pelham Hall Hotel, Brookline (BEA 2430).

CARNEY HOSPITAL

The monthly clinical meeting and luncheon of the Carney Hospital will be held in the auditorium of the Carney Hospital on Monday, January 20, at 11:30 a.m. Medical, surgical and gynecological case reports will be presented.

Physicians and medical students are invited to attend.

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held on Tuesday, January 28, in the amphitheater of the Peter Bent Brigham Hospital at 8:15 p.m. Dr. Elliott C. Cutler will preside.

PROGRAM

Presentation of cases.

Carcinoma of the Pancreas. Dr. Frank Glenn, assistant professor of surgery, Cornell University Medical College.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

There will be a regular meeting of the New England Society of Physical Medicine at the Hotel Kenmore, Boston, on Wednesday, January 22, at 8:00 p.m. An informal dinner will be served in the Empire Room at 6:30 p.m.

PROGRAM

The Clinical Significance of the Electroencephalogram. Dr. Hallowell Davis.

Discussion by Miss Pauline A. Davis and Dr. H. Houston Merritt.

All members of the medical profession are cordially invited to attend.

NEW ENGLAND PEDIATRIC SOCIETY

There will be a meeting of the New England Pediatric Society on Wednesday, January 29. The clinical presentation will be held at the amphitheater, Joseph H. Pratt Diagnostic Hospital, and all other events at Longwood Towers, Brookline.

PROGRAM

4:00 Clinical meeting, Boston Floating Hospital. Dr. Elmer W. Barron and his associates.

6:30 Refreshments.

7:00 Dinner.

8:00 Annual meeting of the society.

Election of officers.

Report of the treasurer.

8:30 Pathologic Aspects of Adiposity. Dr. Sidney Farber.

NEW ENGLAND DERMATOLOGICAL SOCIETY

The next regular meeting of the New England Dermatological Society will be held on Wednesday, February 12, at the Massachusetts General Hospital. The clinic will start at 2 p.m. in the Skin Out-Patient Department.

HAMPDEN DISTRICT MEDICAL SOCIETY

The annual winter meeting of the Hampden District Medical Society will be held on Tuesday, January 21, at 4:00 p.m. in the rooms of the Springfield Academy of Medicine.

Dr. Tracy B. Mallory will present a paper on "Peptic Ulcer Formation" with lantern slides.

Luncheon will be served at 6:30 p.m. at the expense of the society.

MASSACHUSETTS DEPARTMENT OF CIVIL SERVICE AND REGISTRATION

School Physician, \$360 a Year, Lowell

School Physician, \$1000 a Year, Chicopee

Director of State Civil Service, Ulysses J. Lupien, has recently announced that competitive examinations are to be held on March 1 in order to find eligibles for appointment to the positions of school physician, Health Department, Lowell, and dispensary school physician, Health Department, Chicopee.

The entrance requirements are as follows: applicants must be registered physicians under the State Board of Registration in Medicine. The subjects and weights of the examinations are as follows: training and experience, 2; practical questions, 3; total, 5. Applicants must obtain a grade of 70 per cent in each subject in order to become eligible. The last date for filing applications is Saturday, February 15, at 12 o'clock noon.

WACHUSETT MEDICAL SOCIETY

The next meeting of the Wachusett Medical Society will be held on Wednesday, February 5, at the Holden District Hospital at 7:15 p.m. Dr. Chester S. Keefer will speak on "Recent Advances in the Treatment of Meningitis." Dinner will precede the meeting at 6:30 p.m.

NEW YORK UNIVERSITY COLLEGE OF MEDICINE

The date of the annual Alumni Day at the New York University College of Medicine has been changed from the usual Washington's Birthday to March 21 and 22, 1941. At this time, the Alumni Association is celebrating the one-hundredth anniversary of the founding of the medical college.

The program will begin with a dinner for all the alumni and their wives at Hotel Roosevelt on Friday, March 21. On Saturday, March 22, there will be a scientific session at the medical school during the morning and afternoon. There will be a luncheon in the lounge at the medical school, Dr. Nathan B. Van Etten, president of the American Medical Association, will be the speaker.

AMERICAN PUBLIC HEALTH ASSOCIATION

The seventieth annual meeting of the American Public Health Association will be held in Atlantic City, New Jersey, on October 14-17, with the Convention Hall as headquarters for the meeting and the Hotel Traymore as residence headquarters. The American School of Public Health, the International Society of Medical Health Officers, the Association of Women in Public Health, the Conference of State Sanitary Engineers, the Conference of Municipal Public Health Engineers, the Conference of State Provincial Public Health Laboratory Directors and a number of other related organizations will meet in conjunction with the association.

The annual meeting of the American Public Health Association will bring 3500 professional public-health workers to Atlantic City. A New Jersey committee responsible for entertainment, inspection trips and other local aspects of the meeting, is being formed under the direction of Dr. S. L. Salasin, health officer of Atlantic City.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, JANUARY 19

SUNDAY JANUARY 19

11 a.m. How Accidents Happen Dr. Henry C. Marble Free public lecture Harvard Medical School Building D

11 p.m. Various Phases of Plastic and Reconstructive Surgery (illustrated) Dr. Varaztad H. Karanjian Public health lecture Cambridge Hospital Margaret Jewett Hall

MONDAY JANUARY 20

11:30 a.m. Monthly clinical meeting and luncheon Carney Hospital
12:15-1:15 p.m. Clinicopathological conference Peter Bent Brigham Hospital amphitheater

TUESDAY JANUARY 21

9-10 a.m. Vitamin B Deficiency Dr. Stuart Mecklejohn. Joseph H. Pratt Diagnostic Hospital

12 m. The Relation of Pituitary Function and Mental Development Dr. George Levene South End Medical Club Headquarters of the Boston Tuberculosis Association 554 Columbus Avenue Boston

12:15-1:15 p.m. Clinicorontogenological conference Peter Bent Brigham Hospital amphitheater

WEDNESDAY JANUARY 22

9-10 a.m. Hospital case presentation Dr. S. J. Thannhauser Joseph H. Pratt Diagnostic Hospital

12 m. Clinicopathological conference Children's Hospital

*2-4 p.m. Abdominal Pain Drs. Elliott C. Cutler and Soma Weiss Peter Bent Brigham Hospital

8 p.m. Boston Society of Biologists Ether Dome Massachusetts General Hospital

*8 p.m. Clinical Significance of the Electroencephalogram Dr. Hal Lowell Davis New England Society of Physical Medicine Hotel Kenmore Boston

THURSDAY JANUARY 23

*8:30 a.m. Combined clinic of the medical surgical orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital at the Children's Hospital

*9-10 a.m. Fissure in Ano Dr. E. T. Whitney Joseph H. Pratt Diagnostic Hospital

FRIDAY JANUARY 24

*9-10 a.m. Pregnancy Complicating Diabetes Dr. Priscilla White Joseph H. Pratt Diagnostic Hospital

SATURDAY JANUARY 25

*9-10 a.m. Hospital case presentation Dr. S. J. Thannhauser Joseph H. Pratt Diagnostic Hospital

*Open to the medical profession

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Methods of Treatment. By Logan Clendening, M.D., clinical professor of medicine, Medical Department, University of Kansas, and attending physician, University of Kansas Hospitals; and Edward H. Hashinger, M.D., clinical professor of medicine, Medical Department, University of Kansas, attending physician, University of Kansas Hospitals, and attending physician, St. Luke's Hospital, Kansas City, Missouri. Seventh edition. 8°, cloth, 997 pp., with 138 illustrations. St. Louis: C. V. Mosby Company, 1941. \$10.00.

Foreign Bodies Left in the Abdomen. The surgical problems: cases, treatment, prevention. The legal problems: cases, decisions, responsibilities. By Harry Sturgeon Crossen, M.D., School of Medicine, Washington University, St. Louis; and David Frederic Crossen, LL.B., School of Law, Washington University. 4°, cloth, 762 pp., with 212 illustrations, including 4 color plates. St. Louis: C. V. Mosby Company, 1940. \$10.00.

Clinical Pellagra. By Seale Harris, M.D., professor emeritus of medicine, University of Alabama, Birmingham, Alabama; assisted by Seale Harris, Jr., M.D., formerly assistant professor of medicine, Vanderbilt University School of Medicine, Nashville, Tennessee. With foreword by E. V. McCollum, Ph.D., Sc.D., LL.D., professor of biochemistry, School of Hygiene and Public Health, Johns Hopkins University, Baltimore. 4°, cloth, 494 pp., with 66 illustrations and 4 color plates. St. Louis: C. V. Mosby Company, 1941. \$7.00.

Doctor in Arabia. By Paul W. Harrison, M.D. 8°, cloth, 303 pp., with 9 illustrations. New York: John Day Company, 1940. \$3.00.

Diagnosis and Treatment of Menstrual Disorders and Sterility. By Charles Mazer, M.D., assistant professor of gynecology and obstetrics, Graduate School of Medicine, University of Pennsylvania, and gynecologist, Mount Sinai Hospital, Philadelphia; and S. Leon Israel, M.D., instructor in gynecology and obstetrics, School of Medicine, University of Pennsylvania, and associate gynecologist, Mount Sinai Hospital. 8°, cloth, 485 pp., with 108 illustrations. New York: Paul B. Hoeber, Incorporated, 1940. \$6.50.

The Doctor and the Difficult Child. By William Moodie, M.D., F.R.C.P., D.P.M., medical director, London Child Guidance, Clinic and Training Centre. 8°, cloth, 214 pp. New York: The Commonwealth Fund, 1940. \$1.50.

The Endocrine Function of Iodine. By William Thomas Salter, M.D., assistant professor of medicine, Harvard Medical School, and associate physician, Thorndike Memorial Laboratory, Boston City Hospital. 8°, cloth, 351 pp., with 45 tables and 40 illustrations. Cambridge: Harvard University Press, 1940. \$3.50.

Lipidoses: Diseases of the cellular lipid metabolism. By Siegfried J. Thannhauser, M.D., Ph.D., formerly professor of medicine, University Clinic, Freiburg, Germany, associate professor of medicine, Tufts College Medical School, and associate chief, Joseph H. Pratt Diagnostic Hospital,

Boston. Edited by Henry A. Christian, M.D., LL.D., Hon. Sc.D., Hon. F.R.C.P. (Can.), Hersey Professor of the Theory and Practice of Physic, emeritus, Harvard University, and physician-in-chief, emeritus, Peter Bent Brigham Hospital, Boston. (Reprinted from Oxford Loose-Leaf Medicine). 8°, cloth, 370 pp., with 78 illustrations. New York: Oxford University Press, 1940. \$6.00.

Hydrotherapy in Psychiatric Hospitals. By Rebekah Wright, M.D., hydrologist, Massachusetts Department of Mental Health. 8°, cloth, 334 pp., with 91 illustrations. Boston: The Tudor Press, 1940. \$4.00.

Treatment in General Practice. Surgery (continued). Articles republished from the *British Medical Journal*. Vol. IV. 8°, cloth, 562 pp., with 143 illustrations. London: H. K. Lewis and Company, Limited, 1940. 16s net.

A Surgeon's Life: The autobiography of J. M. T. Finney. 8°, cloth, 396 pp. New York: G. P. Putnam's Sons, 1940. \$3.50.

Bellevue. By Lorraine Maynard. In collaboration with Laurence Miscall, M.D. 8°, cloth, 280 pp. New York: Julian Messner, Incorporated, 1940. \$2.50.

BOOK REVIEWS

Behind the Scenes of Murder. By Joseph Catton, M.D. 8°, cloth, 355 pp. New York: W. W. Norton & Company, Incorporated \$3.00.

In the last twenty years the psychiatrist has become an important factor in the medicolegal aspect of homicide. With the gradual passing of the undignified and often useless "battle of experts" for the prosecution and for the defence, the court, in many states, now appoints before trial a psychiatrist or a board of mental experts to examine all persons accused of a capital crime. The findings are available for counsel of each side as well as for the judge. The author of this book has served various courts on the Pacific Coast as an independent expert for the last twenty-five years. His experience has been wide, and many persons of national "notoriety" have come under his observation, such as Mrs. Judd, William Hickman, and the Massies of Honolulu. Each case is separately analyzed, with a brief psychiatric summary of the accused person's reactions under examination. In most cases, the author allows the individual to tell his own story, and much of the book contains what purports to be actual statements and verbatim reports of conversations or exchanges between the witness and the lawyer on the stand.

This is not a learned scholarly account of the subject, but a semipopular treatise designed to interest the public as well as the medical profession. The tone in general is conservative, the author's reactions being well within the usually accepted standards of present-day psychiatry. The style is somewhat flamboyant, but for a discerning reader this should not obscure the basic soundness of the author's contentions. He is a staunch defender of complete psychiatric examination of accused persons, deplors such terms as "temporary insanity" and believes that we are not ready to substitute any known method of psychological third degree, such as "lie detectors" or "truth-telling serum" (scopolamine), for the fifth amendment to the Constitution: "No person charged with a criminal offense shall be forced to testify against himself."

Dr. Catton has no cure for homicide. Given the mental components of a slayer and the proper environment, any person might commit a crime. Constitutional defectiveness, in the psychiatric sense, is commonly found in

most slayers, alcohol and other drugs, the passions of jealousy, lust, rage and sadism, all are frequent environmental factors. Few murderers are insane, and psychiatry can offer little or nothing towards preventing one half the number of murders which are scheduled for tomorrow. Of the other half, early diagnosis and commitment of the 'psychopaths,' many with long criminal records, will help remove what Dr Catton succinctly describes as "an invitation to murder." Other preventive measures are those well known under the general term of "social psychiatry." The main feature of a psychiatric approach to crime prevention should be, in Dr Catton's opinion, clinical group study, such as that carried on by the Judge Baker Foundation in Boston, in addition to continuing, directing jurisdiction over the offender by the clinic. Up to now, as soon as control is relinquished, men again commit crime, even murder. The key to crime prevention is therefore a continued psychiatric supervision.

This thought-provoking book is well printed. It carries an adequate index and a useful appendix with definitions of degrees of homicide, "triability tests," "responsibility tests" and other pertinent matters of law as used in the various states.

Obesity and Leanness By Hugo R. Ronj, M.D. 8°, cloth 300 pp., with 32 illustrations. Philadelphia Lea & Febiger, 1940 \$3.75

The value of this careful monograph lies in its stimulating presentation of the unsolved problems of its subject, rather than in any important discoveries in their solution. Obesity and leanness are rightly viewed as aspects of the same fundamental problem,—namely, why some persons go through life oversupplied with adipose tissue, whereas others, often in an apparently identical environment, remain desperately thin.

The book begins with chapters on the physiology and metabolism of fats in the body, followed by discussions of the caloric balance, the mechanisms of hunger, appetite and satiety, and the specific dynamic action of foods. The role of the endocrines, including the thyroid and pituitary glands and the pancreatic islets, and the influence of the autonomic nervous system and hypothalamus are surveyed. All these factors are related in a conception of homeostatic regulation. The importance of heredity is pointed out.

The later chapters deal with clinical aspects, classification and treatment. One is impressed throughout by the lack of well-established, exact knowledge of any but the most superficial aspects of the problem, and by the difficulty of devising experimental approaches yielding unambiguous conclusions. This study, however, is a challenge and a stimulus for continued work in this field.

The book is lucidly written, but the usage of conjunctions and prepositions is frequently inept. The typography is poor. There is a bibliography at the end of each chapter, and a good index.

Malaria and Colonization in the Carolina Low Country 1526-1696 By St Julien Ravenel Childs 8°, paper 306 pp. Baltimore The Johns Hopkins Press, 1940 \$2.50

The Carolina Low Country extends from Florida to Cape Hatteras, from the coastal area as far west as the mountains. Malaria was formerly so prevalent in this territory that white men could remain there overnight during the fever season only at the risk of their lives. Before 1670, when the Englishmen settled near the present site of Charleston, all the earlier colonies had failed. Malaria was partly responsible, since it occurred in epidemics and often caused marked disability and even death. Later

the disease became endemic, until it gradually died out toward 1700.

Mr Childs has written a finely documented account of the whole subject. His work is full of dependable historical data of medical interest. He gives an excellent account of Dr Nicolás Monardes, of Seville, a voluminous writer, who gave the only definite report of malaria in the Low Country during the period of 1565-1580. His work is best known in this country through its English translation, *Joyfull Newes out of the Newe Founde Worlde* (1577), by Frampton. The first edition, in Spanish, was published at Seville in 1565. A new edition of Monardes was published in 1925.

About one hundred years after Monardes's time, another physician, the Englishman, John Locke, was an important figure in the development of the Carolina colony. He entered the services of Astley Cooper, first earl of Shaftesbury, as a physician. He probably drew up the constitution of Carolina and assisted the promoters in other ways. Neither Cooper nor Locke came to Carolina, and there were few physicians in the Low Country in the early seventeenth century. Toward 1700 many more doctors are listed by Mr Childs in his extensive account of the development of Charleston.

This comprehensive study, with an extensive bibliography and a good index, is a fine example of medical and historical research. It will long serve as the outstanding reference on the subject.

Medical Work of the Knights Hospitallers of Saint John of Jerusalem By Edgar Erskine Hume, M.D. 4°, cloth, 371 pp., with 130 illustrations. Baltimore Johns Hopkins Press, 1940 \$3.00

Although there have been a number of histories of the Knights of Saint John of Jerusalem, no account of the medical work of this old order has ever before been undertaken. The book is therefore a work of primary importance to the medical historian. No one is more fitted for the investigation than Colonel Hume, a Knight of Honor of the order, an accomplished historian, and a physician in the Medical Corps of the United States Army. The book, moreover, has the stamp of the Institute of the History of Medicine of the Johns Hopkins University, and some of the chapters have already appeared in the *Bulletin* of that institute.

Colonel Hume's interest in the order is understandable, for the Knights of Saint John, later called the Knights of Rhodes and the Knights of Malta to signify their travels, were first organized by military medical officers or war-ringing physicians. They were not noncombatants, but a military group who could strike the enemy mighty blows, and yet later bind the wounds of that same enemy as well as those of their own comrades. They went on the Crusades, founded a hospital in Jerusalem as early as 1065, were driven to Rhodes and later to Malta, and finally spread over the world, always taking a Christian part in wars and doing missionary work in distant lands. The British branch was active in World War I, and many will remember the bombing of their hospital at Etaples in 1918.

The book is well produced, with numerous illustrations and an index. It is a fundamental text, and Colonel Hume is to be congratulated on completing a long task. He has traveled far, and much of the medical history of this order is due to his first-hand observation. This is the type of work of which American medical historians can justly be proud.

Pediatrics and Pediatric Nursing. By A. Graeme Mitchell, M.D., Echo K. Upham, R.N., and Elgie M. Wallinger, R.N. 8°, cloth, 575 pp., with 83 illustrations. Philadelphia: W. B. Saunders Company, 1939. \$3.00.

This book satisfactorily covers the ground of pediatric nursing in health as well as in disease. It should teach the nurse not only what to do and how to do it, but the why's and wherefore's of her procedures. In other words, it supplies adequately the pediatric background, without giving her so much material as to tempt her to become an amateur doctor. The writing is plain, simple and direct; explanations and definitions are given where they seem necessary. There are excellent charts and tables, apt and pertinent illustrations, diet lists and diet instructions for different ages and lists of suitable books and toys. Because the book is intended largely for use in training schools, there are problems and questions at the end of every chapter. It is a pleasure to recommend a book that seems so safe, sane and adequate within its field.

Clinical Roentgenology of the Alimentary Tract. By Jacob Buckstein, M.D. 8°, cloth, 652 pp., with 525 illustrations. Philadelphia: W. B. Saunders Company, 1940. \$10.00.

The author has written a most readable text, profusely and excellently illustrated, and containing abundant references to the literature. Unlike many so-called "new" books, the diagnostic criteria applicable to even very recently described technical maneuvers are incorporated. It should be read by all roentgenologists and gastroenterologists. The general practitioner who peruses it will be impressed by the multiplicity of lesions successfully diagnosed by the roentgen method and will receive tangible proof that roentgen diagnosis of disease of the gastrointestinal tract is no longer the simple procedure it was once thought to be, but rather a complex operation requiring special equipment, repeated examinations and specific knowledge on the part of the examiner.

Endocrine Therapy in General Practice. By Elmer L. Sevringhaus, M.D. 8°, cloth, 239 pp., with 49 illustrations. Chicago: The Year Book Publishers, Incorporated. \$2.75.

This small handbook on clinical endocrinology is a welcome addition to the busy physician. The book is clearly written. There is an apparent omission of many scientific details that might have made it difficult to read; however, the chief endocrine disorders are covered clearly so that an understanding of the subject can be accomplished with a minimum of effort. At the same time, the author has made each chapter sufficiently thorough for the complexities of each endocrine problem to be appreciated. The newer knowledge of Addison's disease is included: in every way the book is thoroughly up to date.

The Bacteriology of Public Health. By George M. Cameron, Ph.D. 8°, cloth, 451 pp., with 35 illustrations and 8 color plates. St. Louis: C. V. Mosby Company, 1940. \$3.50.

This is a text of general medical and laboratory knowledge, for the most part accurate, but medically superficial. It is well written, and in places is well documented. It is doubtful if the author could pass the type of bacteriology examination customarily given to second-year medical students in this country. This lack of clinical perspective, as well as of precise knowledge, makes the book useless for medical students, and also for anyone who intends to undertake public-health responsibilities. It may be of value as a college textbook.

Cyclopropane Anesthesia. By Benjamin Howard Robbins, M.D. 8°, cloth, 175 pp., with 40 illustrations and 46 tables. Baltimore: Williams & Wilkins Company, 1940. \$3.00.

This short informative book on Cyclopropane Anesthesia is written by a leading laboratory investigator in the field. The text gives many tables and laboratory findings, with the conclusions drawn from them. These are related to the opinions and findings of clinicians of wide experience. There are chapters dealing with the concentrations of cyclopropane required for anesthesia and with the effect of cyclopropane on the respiratory system, the gastrointestinal tract, the blood and the tissues. Other chapters describe the administration of cyclopropane and discuss its indications, contraindications and complications. In the outstanding chapter—on the effects of this anesthesia on the circulatory system—the author reports his experiments, which show that, in dogs, morphine increases the frequency of cardiac arrhythmias during cyclopropane anesthesia and that certain barbiturates abolish them. It is a valuable and instructive reference work for the specialist in anesthesia.

A Man Who Found a Country. By Dr. A. Nakashian. 8°, cloth, 279 pp. New York: Thomas Y. Crowell Company, 1940. \$2.75.

This pleasantly written and informative book will interest readers who desire to get a first-hand knowledge of the life and work of a Christian subject and physician living under the rule of a Moslem monarch. Dr. Nakashian, an Armenian who obtained his medical degree in 1894, records his unique and dramatic experiences in reaching that goal. The theft of a corpse, sessions with a mad professor, efforts to undermine the strange superstition that examination of the pulse reveals everything, encounters with highway robbers, life in prison and incidents in general practice—all give an illuminating picture of conditions in general in the Near East. Dr. Nakashian writes in an exhilarating style, and the reviewer believes that this book will supply several hours of relaxation and instruction to any physician who may read it.

Handbook of Microscopic Characteristics of Tissues and Organs. By Karl A. Stiles, M.S., Ph.D. 8°, leather, 148 pp., with 9 tabular charts. Philadelphia: Blakiston Company, 1940. \$1.50.

This outline is intended as a supplementary textbook of histology. A major feature is the help it offers to beginners in studying the identification of tissues and organs. Pages are printed only on one side, providing in this manner the opportunity for writing additional laboratory or lecture notes. There are useful tabular charts on the various systems of the body. This is a good guide for students who are preparing for examinations.

Psychiatry for Nurses. By Louis J. Karnosh, B.S., Sc.D., M.D. and Edith B. Gage, R.N. 8°, cloth, 327 pp., with 34 illustrations. St. Louis: The C. V. Mosby Company, 1940. \$2.75.

This is a well-organized and practical book, worth reading even by the person who is not a nurse. It will do very well for the use of social workers and intelligent laymen who want to know facts and not fancies about mental disease.

The style is direct, terse and informative. The authors have done a good job in the preparation of this book, which can be highly recommended.

NUMBER 4

HEAD INJURIES*

Observations Based on a Study of 554 Patients

WILFRED PICKLES, M.D.†

PROVIDENCE, RHODE ISLAND

If thou examinest a man having a gaping wound in his head penetrating to the bone and smashing his skull thou shouldst palpate his wound. Shouldst thou find that smash which is in his skull deep and sunken under thy fingers, while the swelling which is over it protrudes, he discharges blood from both his nostrils and both his ears and he suffers with stiffness in his neck, so that he is unable to look at his two shoulders and his breast.

Thou shouldst say regarding him: One having a gaping wound in his head, penetrating to the bone and smashing his skull, while he suffers with stiffness in his neck.

An ailment not to be treated

Thou shalt not bind him but moor him to his mooring stakes, until the period of his injury passes by.¹

THUS wrote a wise and observant Egyptian physician, possibly Imhotep himself, in the earliest known surgical record, well over four thousand years ago. The interest in this striking type of injury has continued through all the years down to the present time. I am accordingly presenting some observations as to treatment based on a study of 554 patients in the Rhode Island Hospital during the past five and a half years.

So far as I can determine, a Rhode Island physician, Henry E. Turner, of Newport, was probably the first to suggest the deliberate opening of the dura in order that the pressure accompanying these injuries might thereby be relieved. In a paper presented to the Rhode Island Medical Society in December, 1861, he² reported two severe head injuries: the first to his brother, who had wide laceration of dura and brain, and recovered; the second to a seaman, who had a depressed fracture without injury of the dura, and died. He questioned 'whether the penetration of the dura mater did not, in my brother's case,

relieve the brain from the pressure, which, in the other case, proved fatal.' In the following year, he³ wrote

I have been thus particular in giving an account of this case, as it furnishes a pretty good commentary on the doctrine I ventured with some hesitation, to enunciate a year ago that, in severe injuries of the head perforation of the dura mater improves the prospect of relief and final recovery. I should not feel justified in opening the dura under such circumstances, but I think the question of its propriety worthy of investigation and discussion.

About thirty five years later, Horsley⁴ did have the courage to open the dura deliberately to relieve intracranial pressure, and still later Cushing⁵ worked out the technical details that have made subtemporal and suboccipital decompressions such valuable aids in treating diseases within the head.

At the Rhode Island Hospital, patients with head injuries are admitted to the Surgical Service. Such cases comprise a mixed group. Forty four per cent are due to automobile accidents, 36 per cent to falls, 11 per cent to blows on the head and the rest to various causes, with industrial accidents accounting for less than 2 per cent. These patients are always seen in consultation by the Neurological Service and the Eye Service, and by other services as needed. The treatment that we now follow has thus grown gradually as a result of close co-operation between these departments.

Treatment of head injuries is primarily the treatment of brain damage. Complications such as fracture, hemorrhage and infection may arise and may mask or completely outshadow the injury to the brain, but it is essential that we hold to the general conception of brain damage. This damage, of course, varies within wide limits, and it is convenient to divide it clinically into three syndromes: those of concussion, congestion and contusion. These degrees of damage merge into one another—there is no sharp line of demarcation.

†Associate surgeon, Surgical Service, and surgeon, Neurosurgical Division, Surgical Service, Rhode Island Hospital.

Following an injury of the head, the patient with concussion has a loss of consciousness from which he recovers completely. All other findings are normal, there are no neurologic signs, and the evidence given by lumbar puncture is completely negative. Patients with this syndrome have made up 4 per cent of our series.

The patient with congestion has, in addition to his concussion, headache, nausea, vomiting, dizziness, confusion and possibly loss of memory. Lumbar puncture shows elevation of pressure, but the fluid itself is normal. Forty-seven per cent of our patients were classified as in this group.

Contusion is considered to be present when there are added to the signs of congestion evidences of more serious brain damage. There may be coma with loss of sphincter control, respiratory distress, delirium, convulsions and shifting localizations of all sorts. Many of these patients are in shock. Lumbar puncture shows bloody fluid, usually under increased pressure, although this may be lowered by the presence of shock or dehydration. Forty-nine per cent of our patients were thought to have some degree of contusion.

Our aim in treatment is to get the patient at rest with a normal intracranial pressure as soon as this can be done safely. If he is in shock, this must be remedied first of all. Blankets and heaters are used to conserve body warmth, black coffee is given by rectum, and caffeine sodium benzoate is given subcutaneously. The two latter agents serve a double purpose: they not only act as general stimulants but help to control pressure within the head. Handling of the patient is limited as strictly as possible. If clothing is to be removed, this is done gently under blankets. No attempt is made to do a thorough examination or a lumbar puncture or to take x-ray photographs. Lacerations are covered with sterile dressings and their repair left until later, unless hemorrhage has to be checked. And so, with the patient suffering from head injury and shock, we follow the advice of the early surgeon and "moor him to his mooring stakes, until the period of his injury passes by."

When the period of shock has passed, we can begin to make a careful estimate of the extent of the damage to the brain. In addition to the usual clinical chart, an hourly record of pulse and blood pressure is kept, and the fluid intake and output are recorded. A thorough physical examination is made, and lacerations of the scalp are explored with the gloved finger for fracture or depression. A complete examination is made by a neurologist, and the eyes and eyegrounds are examined by an ophthalmologist. Lumbar puncture is next done under complete aseptic precautions,

a water manometer being used to record the pressure. Care should be taken to see that the patient's head is not too sharply flexed, since failure to observe this precaution may result in jugular compression, which will raise the intracranial pressure. This will not only give false information but will aggravate the condition for which relief is sought. If the pressure is moderately increased, it is our practice to remove enough fluid to bring it down to a normal level; if it is grossly increased, we bring it about halfway to normal at the first puncture, using further punctures to bring it more gradually to a normal reading. We think that this precaution is of value in avoiding possible further damage from a too-sudden shift in pressure. The frequency with which punctures are done depends on the amount of pressure, the presence or absence of blood and the response to the taps. We have punctured as often as once in six hours when this has seemed necessary. In any case, our aim is to record clear fluid, with cell count, protein and pressure normal at the final puncture. A careful cell count is important, because many fluids reported grossly clear show an appreciable number of red cells when these are counted. If we suspect that a patient has an extradural hemorrhage, we do not use lumbar punctures until after the bleeding has been controlled, since an earlier reduction of pressure may increase the hemorrhage. If the patient has drainage of spinal fluid from the ear, nose or pharynx we are reluctant to use punctures until this stops, because reduction of pressure may result in a reverse flow with a greater possibility of infection. We also believe that the leakage itself helps in reducing the pressure.

As aids in the control of pressure we use careful and moderate dehydration by limitation of fluids, intravenous concentrated glucose solutions and intramuscular magnesium sulfate, bearing in mind that overenthusiasm in the use of any of these methods may bring about a toxic dehydration, and that renal damage may be caused or aggravated by hypertonic solutions. If a combination of all these methods fails to reduce the pressure, subtemporal decompression may be performed; but its results, except when subdural hematoma is present, are disappointing. We think that this method is rarely needed.

Drugs are used sparingly in brain damage. Morphine is not used at all, since it has a real effect in increasing intracranial pressure and depressing respiration. For persistent headache we employ acetylsalicylic acid in combination with caffeine; for moderate sedation, pentobarbital-sodium; and for active delirium, sodium pheno-

barbital intramuscularly or paraldehyde by rectum.

Thus far we have considered the problem of brain damage and its treatment, by far the most important consideration in head injuries. But there are, of course, complications. Fracture of the skull was demonstrated in a little over 25 per cent of the patients in this series; the actual incidence must be considerably greater, since all fractures are not shown by x-ray, and all patients, for one reason or another, are not examined by x-ray. The presence or absence of fracture, except of special types, is usually considered to be of little moment. It is interesting to note that the mortality of patients with fracture was 9 per cent, considerably higher than the mortality for the entire series, which was a little under 5 per cent. Linear fractures of the vault showed a mortality of less than 4 per cent, whereas those of the base showed a mortality of 37 per cent. These fractures call for no treatment other than that of the associated brain damage. Fractures extending into the nasal accessory sinuses are potentially more serious because of the possibility of infection; we had 3 such fractures, but no deaths from this cause. Fractures involving the mastoid carry the same risk; we had 7 such fractures, 3 of them requiring operations on the mastoid, with 1 death. Recently developed drugs are of great value in treating infection coming from this cause, we have had a patient with severe meningitis recover completely following the use of sulfapyridine.

Depressed fractures need operative treatment. When they are compound, their presence can often be made out by the palpation previously advised, and operation is undertaken as soon as shock and brain damage will permit. Thorough débridement and generous flushing of the wound with warm saline solution are of great help in reducing infection. In children the depressed area can often be snapped back into position by means of an elevator introduced through a small drill hole. In older people, the depressed fragments are not infrequently locked. In some cases we have found it possible to free this locking by making a drill hole at the point where the lines of fracture come together; in others, we have gained this end by widening the lines of fracture by the use of DeVilbiss forceps. Free bone fragments are removed, and the resulting bone defect is left for possible later plastic repair. The wound in the scalp is closed without drainage.

Simple depressed fractures can be left for elevation until the patient is in good general condition. Their diagnosis is more difficult, but careful tangential x-ray films are of great help. In our experience, the degree of depression found at

operation is almost always greater than the x-ray films indicate. The mortality in simple depressed fractures depends on the underlying brain damage; in our patients with compound depressions it has been 25 per cent.

When a patient after initial unconsciousness clears for a period and then lapses again into unconsciousness, he presents the classic picture of extradural hemorrhage. This is usually due to rupture of the middle meningeal artery or of a venous sinus, and calls for immediate operation. After determination of the side involved, a subtemporal decompression is performed, the clot is removed and the bleeding artery clipped or tied with silk. If this is not possible, the foramen spinosum can be plugged with wood or cotton and the artery thus obliterated. Sinus bleeding can usually be controlled by a muscle patch. If extradural bleeding is the chief injury, the results of the operation are very good, but there is often associated severe brain damage. Our mortality has been 50 per cent.

The existence of a subdural hematoma should be suspected when a patient with head injury not of the overwhelming type fails to improve under the treatment already described, and it is chiefly to the work of Munro⁶ that we owe our knowledge of this complication. The diagnosis can be established only by temporal trephine, bilateral if needed. Observation of the dura through such an opening is not enough, the dura is opened and the hematoma is treated by the methods that he has described so well. The mortality of this complication is influenced to a considerable degree by the severity of the brain damage, in our patients it has been 22 per cent.

SUMMARY

Observations are presented on the treatment of head injuries based on the results of a conservative method followed at the Rhode Island Hospital in caring for 554 patients during the last five and a half years, with an operative incidence of 6 per cent, an operative mortality of 29 per cent and a gross mortality of slightly under 5 per cent. 184 Waterman Street

DISCUSSION

DR. DONALD MUNRO (Boston): It is gratifying that somebody who has not shown the bad judgment to pin the tag "specialist" on himself has taken up the study of these very common conditions, which, after all, ought to be handled almost exclusively by the general surgeon. I congratulate Dr. Pickles on his mortality figures, and I congratulate you who are here on having had the opportunity to hear such a brilliant and satisfactory presentation.

I am in complete agreement with him except for two points. The first is his additional use of dehydration in the treatment of brain injury. I believe that the use of dehydration in the treatment of brain injury should be limited to the very first part of the treatment, perhaps not extended beyond the first forty-eight hours after the injury; after that the use of dehydration does more harm than good. I am convinced by my experience that the limitation of fluids by mouth, or by any other way, is a mistake, and I have for some years made it a rule that the minimum amount of fluid that an adult patient with a head injury gets is 5000 cc. every twenty-four hours. I believe that less than that is not adequate to care for the fluid needs of such patients.

The second point on which I am in disagreement with him is about irrigation of the wounds in the treatment of compound fractures. I think that the irrigation of wounds in compound fractures of the skull is contraindicated; I never use it. That, however, brings me to a debatable part of the treatment of head injuries, a part that many of the specialists are in disagreement about, and one in which I have very definite and fixed ideas, that is, the problem of when and how to operate on compound fractures of the skull. There is a rather general opinion that compound fractures of the skull are emergencies. My experience and opinion are that they are not emergencies, if you mean by an emergency that the patient must be operated on as soon as seen. I feel very strongly that these patients practically never need to be operated on until such time as you can make your operation an elective procedure. In that event, you have forty-eight hours from the time they are injured until the time they must be operated on.

In support of that viewpoint I invite your attention to the fact that the problem of compound fractures of the skull deals not only with the mortality but also with the morbidity from sepsis after the fractures have been treated. In relation to this I have been using in my clinic the same technic for the last ten years. Everyone who works on compound fractures of the skull in my clinic does every case the same way.

This treatment is always carried out by doing a complete débridement with no local treatment previous to that except for the putting of a dry dressing on the wound. The débridement is done in such a way as to produce an expected healing of the wound by first intention. Unless it does so heal, we class it as septic, even if it merely contains a granulating area. Exception to that is made with cases with frontal-sinus involvement in which the supra-

orbital ridge has been involved. In such cases the wound is drained.

I have had a total of 176 cases of compound fractures of the skull, 13 of them from bullet wounds and 25 with involvement of the frontal sinus or cribiform plate. Some of these cases have died within twenty-four hours, mostly of surgical shock. In a study of mortality figures, one must consider the incidence of twenty-four-hour deaths, which in this series was 15 per cent. The total mortality for the whole 176 cases was 28 per cent. If we exclude the twenty-four-hour deaths, it was 13 per cent.

One hundred and thirty, or 74 per cent, of these 176 cases were operated on, with a mortality of 15 per cent. A study of the operated cases and the cause of death in relation to the correctness of the technic in operating on them has demonstrated that all but 6 per cent of the deaths were due, or could be traced directly, to faulty technic in the treatment of the wound. I believe that the operative mortality in compound fracture of the skull should not rise above 10 per cent, and may well be brought lower than that.

Thirty-two, or 25 per cent, of the 130 operated cases were septic. By that I mean that the wounds granulated and healed by second intention or that abscesses, osteomyelitis or meningitis developed. If the cases which were septic because of technical errors are excluded, the percentage of sepsis drops to 5 per cent. I think that is probably somewhere near the irreducible minimum that is bound to accompany any method of treating compound fractures of the skull.

These figures are significant because they represent a unified experience with a considerable group, and serve to annotate Dr. Pickles's excellent paper.

DR. EDWARD H. RISLEY (Waterville, Maine): I should like to get an expression of opinion as to the danger or lack of it in doing lumbar punctures in cases which are bleeding. This seems to be an open question.

DR. PICKLES (closing): On the question of dehydration, I apparently did not make myself clear. We attempt it only when other methods fail; that is, when repeated lumbar punctures and ordinary care fail to hold down pressure, we limit fluids and use intravenous glucose and magnesium sulfate. If we use these agents to dehydrate, it seems illogical to push in fluids by mouth at the same time. We do not use dehydration unless we are pushed to that point.

As to the irrigation of wounds, I am afraid that I shall have to differ with Dr. Munro, although his experience is much greater than mine. I have found it a most useful means of converting a dirty, potentially septic wound into one, which can be closed by complete suture and which will heal by first intention.

As regards the use of lumbar puncture when the patient is bleeding, its restriction applies only when we believe that there is a definite extradural hemorrhage; although this may be a theoretical consideration, we still think that it is not necessary, that it does not do any particular good because one is going to operate anyway, and that it may do harm.

ENTEROBIASIS: ITS INCIDENCE AND SYMPTOMATOLOGY
IN A GROUP OF 505 CHILDREN*

THOMAS H. WELLER, MD † AND CHARLES W. SORENSON, MD †

BOSTON

THE development of a simple and accurate method for the diagnosis of pinworm infection has made possible valuable additions to our knowledge of the distribution of the parasite, *Enterobius vermicularis*. Accumulating evidence shows that *E. vermicularis* is one of the commonest parasites in human beings in the United States. However, no survey has yet been made to determine its incidence in the New England area, and comparatively little is known about the symptomatology of enterobiasis. This paper presents the results of a study of the incidence and symptomatology of enterobiasis as encountered in a group of 505 children.

METHODS

The study of the incidence was made on a group of 505 white patients from two to twelve years of age at the Children's Hospital in Boston. These children were divided into two groups: 118 patients studied on the medical wards, and 387 patients examined in the Medical Outpatient Department. Consecutive patients were examined without selection as to age, sex, or type of illness. Information was obtained regarding the age and sex of each child and the number of persons in his family, the latter being divided into those under fourteen years and those fourteen or over.

Determination of the presence of pinworm infection was made by using the cellophane tipped anal swab devised by Hull,¹ generally known as the "NIH swab." This swab consists of a small glass rod, over one end of which a one inch square of cellophane is folded and held in place with a rubber band. For convenience, a one-holed rubber stopper is placed on the other end of the rod, and the swab is thus fitted into a small test tube that serves as a container. In taking the swab the cellophane tipped end is swept over the perianal skin, with the swab held parallel to the skin to take advantage of the scraping properties of the folded edges of the cellophane. In preparing the swab for examination a drop of N/10 sodium hydroxide is placed on a glass slide, the cellophane tipped end of the swab

is placed in the drop, and the rubber band is pushed up with a pair of forceps, thus releasing the cellophane, which is then flattened on the slide. A cover slip is applied to complete the mount. Microscopical examination will detect the ova among the epithelial debris. Since the female pinworm lays its eggs on the perianal skin, this is the obvious site from which to recover eggs for diagnostic purposes. The NIH swab appears to be a highly efficient and accurate means of carrying out such a procedure. Sawitz et al.² found that it was four times as effective as the methods using stool examinations, Faust et al.³ found it five times as efficient as any other means of diagnosis.

Our swabs were taken between 9:00 a.m. and 5:30 p.m. and examined on the same day. In no case were they taken before the morning toilet—a fact that must be considered in evaluating the results. In 90 unselected cases a second examination was done after an interval of two to seven days. The debris adhering to the cellophane was systematically surveyed, using a magnification of 100, when objects resembling ova were seen, the identification was checked with a magnification of 450. No difficulty was encountered in distinguishing the ova, although ova like artefacts in the cellophane, such as those described by Reedon,⁴ were occasionally seen.

The study of the symptomatology was made on 387 patients seen in the Medical Outpatient Department. Consecutive admissions were surveyed to avoid selection. An arbitrary list of eleven of the signs and symptoms most frequently ascribed to pinworm infection was selected for study. A brief history of the symptoms was taken from the adult accompanying the child. Because none of the patients who came to the hospital complained primarily of pinworm infection, an attempt was made to evaluate the history and to disregard those symptoms for which the primary illness provided an adequate explanation. Information was obtained regarding the past and present history of pinworm infection, after which the perianal region was examined for cutaneous lesions and an NIH swab was taken.

In a group of children who were patients on the medical wards, the blood studies done as a part of the routine medical examination were reviewed to see if there was an eosinophilia. This group

*Contributed from the Department of Comparative Pathology and Tropical Medicine and the Department of Preventive Medicine, Harvard Medical School.

†Formerly fourth year student, Harvard Medical School.

was composed of 28 swab-positive and 96 swab-negative children.

RESULTS

Incidence

In the group of 505 children examined, 97 (19 per cent) were found to have enterobiasis. The age and sex distribution of these cases is summarized in Table 1. The relation between the

families of the 91 positive cases was 3.1; in the 396 negative cases the average number was 2.2. Additional data showed that for 91 positive cases the average total family size was 5.5 persons, and for 394 negative children 4.6 persons.

In a group of 387 children, 42 (11 per cent) gave a history of previous pinworm infection, and of these 16 (38 per cent) proved to be positive on swab examination. In the 345 children with no history of infection, 56 (16 per cent) were positive. With a different form of analysis it was found that in the 72 cases that were positive on swab examination, 56 patients (78 per cent) gave no history of pinworm infection.

Only a small group of children were examined a second time. Thus, of the total series of 505 children, 415 were examined by one swab, of which 74 (18 per cent) were positive; of 90 children examined by taking two swabs, 23 (26 per cent) were positive.

Symptomatology

The study of the symptoms was made on 387 children, 72 (19 per cent) of whom had pinworms, and 315 (81 per cent) of whom were swab-negative. The data on the symptomatology were analyzed in two ways: first, by comparison of the symptoms presented by the positive and swab-negative children (these results are summarized in Table 3 and are discussed below); secondly, the

possibility of a correlation between the sex of the patient and the symptomatology was considered in a group of 190 boys, of whom 29 were positive, and 197 girls, of whom 43 had pinworms. This study showed no significant sex variation.

In regard to the relation between the time of day and the intensity of symptoms, 4 of the 315 swab-negative and 3 of the 72 swab-positive patients reported a nocturnal increase in intensity. None of the children gave a history of diurnal increase in symptom intensity. The blood picture was reviewed in 124 patients, 28 of whom had enterobiasis. None of the positive cases showed an eosinophilia of more than 5 per cent.

DISCUSSION

Incidence

Comparatively few reports on the incidence of enterobiasis have appeared in the literature. However, the limited evidence now at hand indicates

that the infection is commoner than has been suspected. The results of the surveys on children in which the NIH swab has been used are summarized in Table 4. Of these, the studies of

TABLE 4. *Studies on the Incidence of Enterobiasis in Children in the United States.*

AUTHORITY	NO. OF CASES	PER CENT POSITIVE	METHOD*	GROUP

Cram and Nolan ¹⁰	106	55	Multiple swab	Nursery school
Switz et al. ²	131	96	Multiple swab	Charitable institution

*The NIH swab was used in all the studies.

Bozicevich,³ Cram et al.⁶ and Bozicevich and Brady⁷ were carried out on patients who were not exposed to the constant opportunities for contact infection that might occur in an orphanage or boarding school; therefore, in this respect their results are comparable to those of the present study. However, in other respects these studies are not comparable with ours, for there are two factors that have probably resulted in our obtaining an infection rate that is misleadingly low. In the first place, the majority of the children were examined by means of only one swab. Cram and Reardon⁶ state that at least one swab should be taken on each of four days before negative findings can be considered to represent a probable absence of pinworm infection. Bozicevich and Brady,⁷ using this system, found that the first swab detected 68 per cent of the positive cases. In the first place, the majority of the children were the incidence from 18 per cent to 26 per cent. The second factor is that the swabs were not taken at the optimum time for the recovery of pinworm ova, since the examinations were made after the morning toilet had been completed.

In the present series, 23 per cent of the girls were infected, as compared with 15 per cent of the boys. Analysis of these figures shows that this difference is 2.2 times the value of the standard error of the difference of these proportions and is statistically significant. This finding is at variance with that of Cram et al.,⁶ who found a slightly higher incidence in males. In comparing age and incidence of infection it was found that enterobiasis was less common in the younger children: 13 per cent of those of two to four years, 23 per cent of those of five to nine and 20 per cent of those of ten to twelve were infected. A statistically significant variation could be established be-

tween the two-to-four-year and five-to-nine-year groups, the difference between the proportions being 2.8 times the value of the standard error of the difference. This observation is in accord with the findings of Cram et al.,⁶ who noted that the incidence was lower in the preschool group than in children of school age.

The familial nature of enterobiasis is well established, but unfortunately is often ignored when instituting specific therapy. Because of the multiple opportunities for infection and reinfection within the household group, it is to be expected that as the family size increases, thus enhancing the chances of acquiring an initial infection, there should be an increase in the incidence of enterobiasis. Bozicevich and Brady⁷ were able to demonstrate a correlation between family size and incidence of infection. In the present study, the average number of children in the households of the positive cases was found to be 0.9 greater than in the households of the negative cases. This difference between the means is 4.8 times the standard error of the difference, and indicates that the incidence is definitely related to the number of children in the family. A similar relation was found to exist when the total family size was considered.

Symptomatology

In the present series, the children with pinworms complained of gastrointestinal symptoms no more frequently than the uninfected children, with the exception of a slight but not significant variation in "loss of appetite." Likewise, vulvitis and night restlessness occurred with the same frequency in both groups. Anal pruritus, perianal skin lesions, enuresis and masturbation were slightly commoner in the positive group, but in no case was the variation statistically significant.

Brady and Wright⁹ presented the first statistical analysis of the symptomatology of this disease. They concluded that anorexia, night restlessness and insomnia were the significant symptoms, and found a slight but not statistically significant eosinophilia in the positive group. However, the group studied did not come from the general population but included "persons seeking treatment for known pinworm infestation" and "persons referred because of symptoms suggestive of oxyuriasis." Therefore, their findings are not comparable with those of the present study.

The relatively asymptomatic nature of the infection in the group of children examined in the present study is interesting. It would appear that subclinical enterobiasis is a common condition. Such a conclusion seems to be adequately substantiated by the fact that of the 72 positive cases, 64

per cent had no gastrointestinal symptoms, 80 per cent had no perineal symptoms, 58 per cent had no nervous symptoms and 36 per cent had none of the symptoms in these three groups. Very similar figures were obtained in the negative group.

These findings must not be construed as meaning that the pinworm is incapable of causing symptoms—in the present series 4 cases showed a symptom complex approximating that of the classic description of enterobiasis. However, it is quite probable that at least two factors have combined to overemphasize the importance of symptoms in this disease. In the first place, the symptoms tend to be misleading; they are for the most part so vague that a positive history could probably be elicited from a large percentage of the normal population. In the second place, in the past only those patients showing symptoms have been studied, for the diagnosis of enterobiasis was usually made after investigation of a suggestive train of symptoms. Further work is necessary to determine why some patients have symptoms and others do not. Perhaps factors such as the intensity of infection, the nervous constitution of the infected person and an allergic response to products of the parasite will be found important.

SUMMARY

In a series of 505 white children examined by the NIH swab technic, the incidence of enterobiasis was 19 per cent.

A significantly higher incidence of infection was found among the 257 girls, 23 per cent being positive, as compared with 15 per cent of 248 boys.

In the total series, the incidence in the two-to-four-year group (13 per cent) was significantly lower than that in the five-to-nine-year group (23 per cent).

A significant difference was found between the average number of children under fourteen years (3.1) in the families of the positive cases and that (2.2) in the families of the negative cases; there

was a similar difference in the total family size (5.5) of the positive cases and that (4.6) of the negative cases.

Seventy-eight per cent of the positive cases gave no history of previous pinworm infection.

The symptomatology of enterobiasis was studied in a group of 387 children, of whom 72 (19 per cent) had pinworms. Anal pruritus, anal skin lesions, enuresis, loss of appetite and masturbation were slightly commoner in children with pinworms; however, the difference between the incidence of these symptoms in children in whom ova were demonstrated and in those in whom none were found was not great enough to be statistically significant. Nausea and vomiting, vague intestinal pain, diarrhea, weight loss, vaginitis and night restlessness were not found more frequently in the swab-positive than in the swab-negative group.

These results indicate that a large proportion of the cases seen in this group were essentially asymptomatic, and that a condition that might be termed subclinical enterobiasis is relatively common.

CONGENITAL ANOMALIES OF THE PELVIC ADNEXA

JOSEPH D. FERRONE, M.D.*

BOSTON

CONGENITAL anomalies are caused by errors in development, and for that reason, any consideration of anomalous structures of the pelvic adnexa may well be prefaced by a brief review of the embryology involved.

In the embryo, the mesonephros is found along the posterior wall of the celom—the future peritoneal cavity. As it develops from its retroperitoneal position it pushes the peritoneum forward, thus forming the urogenital fold, which contains the precursor of the genital gland as well as the wolffian duct and the müllerian duct. The genital gland gradually separates itself by a longitudinal fissure, and after acquiring a mesentery, becomes the testis or ovary. In the female, the retrogression of the wolffian body and duct begins at the seventh or eighth week and continues until nothing but rests remain in the broad ligaments, constituting the parovarium. From the müllerian ducts, however, is developed the entire genital tract to the vaginal introitus. At first the ducts are solid cords; later they invaginate and acquire a lumen. Meanwhile they grow downward until they get below the crest of the ilium, when they turn sharply toward the midline and fuse, forming the utero-vaginal primordium.^{1,2} At the end of the fifth month, the fundus of the uterus normally rounds out, so that all appearance of the former double character of the uterine body disappears.³ The cranial ends of the müllerian ducts form the fallopian tubes, and the open ends develop a series of projections, the fimbriae. The middle and caudal thirds, which have fused, form the corpus of the uterus, the cervix and the upper two thirds of the vagina.

When the caudal ends of the apposed müllerian ducts fail to fuse, one sees, of course, all sorts of malformation, such as uterus didelphys, uterus arcuatus and uterus bicornis.⁴ Less often the cranial ends of the ducts fail to develop properly and other anomalies appear. Rudimentary tubes and ovaries are found,⁵ or the adnexa may be entirely absent.⁶⁻⁸ The tube may be a stub at the cornu of the uterus, whereas the ovary may be found anywhere in the pelvic cavity,⁹ posterior peritoneal wall, inguinal canal, labia majora¹⁰ or uterine wall.¹¹

Some interesting theories concerning the evolution of these malformations have been advanced by Masson and Kaump.⁴ Their excellent paper includes the following classification of the anomalies of the tubes, ovaries, uterus and vagina.

I. Simple reduplication

A. Incomplete joining of the müllerian ducts

1. Symmetrical false reduplication: uterus didelphys

B. Complete joining of the müllerian ducts

1. External junction, internal partition: uterus septus duplex

II. Rudimentary development

A. Aplasia

1. Incomplete development of both sides (symmetrical)

(a) Absence of tubes, uterus or vagina

2. Incomplete development of one side of uterus: uterus unicornis

B. Hypoplasia

1. Symmetrical or asymmetrical development with hypoplasia or one or more parts

III. Atresia of vagina, cervix or fundus of the uterus

The following case is illustrative of one type of pelvic anomaly.

CASE REPORT

E. E., a 21-year-old, married woman, presented herself in June, 1936, complaining of pain in the lower abdomen, especially on the left side, a sense of pressure on the rectum, dysmenorrhea and menorrhagia. In September, 1934, she had given birth to a premature infant weighing 4 pounds, 4 ounces, who was living and well. One year later she began to complain of pain throughout the lower abdomen, much more marked on the left side, and a sensation of pressure on the rectum. About this time dysmenorrhea developed, and the periods lasted longer than before (6 to 10 days), were more profuse and came oftener.

Physical examination revealed a well-developed and well-nourished young woman. The general examination was not remarkable; there was diffuse tenderness throughout the left side of the lower abdomen, and vaginal examination revealed a multiparous introitus with good support. The cervix had slight bilateral nicks but was otherwise not unusual to touch or sight; the os was closed. The uterus could not be made out clearly. The right vault was normal; in the left vault there was a mass which was spindle-shaped, movable and tender and thought to be either an ovarian cyst or a tubo-ovarian mass. A blood Hinton test was negative, as was a Schwartz-McNeil complement-fixation test.

Under treatment the symptoms were somewhat relieved, although the mass persisted. About one year later, in the spring of 1937, the patient returned complaining that the symptoms were more pronounced. Examination at this

*Clinical instructor in obstetrics, Boston University School of Medicine; assistant in obstetrics, Tufts College Medical School; assistant in obstetrics, Harvard Medical School, and junior visiting obstetrician, Newton Hospital.

time was essentially the same as that previously recorded, with the spindle-shaped mass persisting apparently unchanged. At that time exploratory laparotomy was suggested.

At operation at the Newton Hospital in August, 1937, the abdomen was opened. Examination of the pelvis revealed a uterus unicornis, which was located in the left side of the pelvis and which, with the left broad ligament and the left tube and ovary, constituted the mass consistently felt on previous examinations. There was no broad or round ligament attached to the right side of the uterus. Above the pelvic brim near the right iliac fossa, partly covered by terminal ileum and cecum, was a rudimentary right tube and ovary; the latter, though smaller than normal, was apparently functioning normally, be-

days following operation; she had been relieved of the sensation of pressure on the rectum. Seven months later after the operation she returned with a complaint of amenorrhea since discharge, and examination revealed that she was 2 months pregnant, despite 7 months of amenorrhea. In October, 1938, she was delivered of a normal baby weighing 7 pounds, 1 ounce, by low forceps after an easy labor of 6 hours. The mother and baby are now well, although the uterus is slightly to the left of the midline.

It is extremely difficult to determine or even estimate the frequency of pelvic anomalies in women.^{4, 12-15} One thing is certain after review-

FIGURE 1.

cause there was a corpus hemorrhagicum present. These organs were attached to the posterior peritoneum by a stalk, but the fimbriated end of the rudimentary tube was facing the midline (Fig. 1). The appendix was removed as a routine procedure. To relieve the sensation of pressure on the rectum and the pain in the left lower abdomen, an attempt was made to suspend and straighten the uterus by placing two No. 2 chromic catgut sutures in the corner of the uterus where the right round ligament would ordinarily be situated and, after scarifying that area, by pulling it up to what was thought to be a fairly good position, against the anterior parietal peritoneum and slightly to the right of the midline. The ectopic right tube and ovary were not disturbed.

The patient had an uneventful convalescence, including a normal menstrual period, and left the hospital 16

ing some of the literature: there are few if any cases that are absolutely identical. The commonest types are those involving the uterus itself. Findley¹³ in his paper on uterus didelphys quotes other authorities who place the incidence of this abnormality at 1 in 740 women, of which only 3 in 19,000 are recognized clinically. Haynes¹⁴ reports 11 cases, Dannreuther,¹² 13. Masson and Kaump⁴ report a number of cases found at autopsy, but do not record how many protocols were examined. However, the congenital anomalies of the organs developing from the cranial end of the müllerian ducts or the genital glands are much less common, as has been previously

mentioned. Mayo and Knepper⁵ report 6 cases of congenital anomaly of tube and ovary (either or both) in twenty-seven years of experience. In two, rudimentary tubes were present; in the others, neither ovary nor homolateral tube could be found. White⁸ discovered 17 cases of anomaly of tube and ovary in the literature. Others^{6,7} report cases of congenital absence of tube and ovary, but Drosin⁹ and Mauro¹⁰ bring to light cases of ectopia of these organs. In the 2 cases reported by Mauro the ovary was found in the labium majus. Rudauv and Durante¹¹ describe a case in which only the histologic examination of the uterus uncovered an atrophic ovary and tube, buried in the uterine wall on the left side. These facts make one wonder whether every reported case of absence was authentic, or whether more extensive exploration would have uncovered these organs. All these writers stress the fact that abnormalities of the kidney and ureter on the affected side are not uncommon; but an intravenous pyelogram taken in the case reported above showed that both kidneys and ureters were present and normal. In an attempt to explain the anomaly herein reported on the basis of the embryology involved, I should say that the uterus unicornis was evolved entirely from the left müllerian duct. The right müllerian duct never succeeded in working its way caudad to join its partner, but its cranial end continued to develop, resulting in a rudimentary, ectopic right tube and ovary.

An analysis of the records at the Newton Hospital from 1923 to the present reveals that a diagnosis of double uterus was made in 2 cases, that of bicornuate uterus in 1 and that of absence of the fallopian tube in 1. In the latter case, to quote from the operator's note: "The fundus lay to the right of the pelvis. The right tube and ovary showed no abnormality. There was no left tube, and the left ovary was high on the left pelvic wall. A semblance of broad ligament extended from the ovary to the level of the internal os, where a very rudimentary round ligament could be made out. Nothing could be found which represented a rudimentary tube."

The records of the Boston City Hospital were reviewed from 1915 to the present with the following results: the diagnosis of double uterus was made in 9 cases; that of bicornuate uterus, in 7; that of septate (or double) vagina, in 5, and that of congenital anomaly of the tubes and ovaries, in 4. An analysis of the last 4 cases revealed the following: in one no pelvic organs were found (there was a vagina but no uterus, tubes or ovaries); the second had a congenital absence of the

left ovary and a rudimentary left tube; the third was the same as the second except that a nodule the size of a lima bean was excised from the left posterior peritoneal wall and the pathologist reported it to be a normally functioning ovary; the fourth had a congenital absence of the right appendages, a uterus unicornis and a pelvic right kidney. An attempt to estimate the frequency of these abnormalities from the above figures might lead to erroneous conclusions.

The chief points of practical interest are: Can diagnoses of pelvic anomalies be made in advance and if so, how? What is the proper treatment? Most women who have such anomalies lead a perfectly normal existence, except when the vagina is involved. The history alone is not very helpful; pelvic pain, menorrhagia, metrorrhagia, alone or in combination, are frequent complaints. Undoubtedly some abnormalities can be suspected and perhaps even diagnosed at the time of a pelvic examination, particularly the reduplicating forms. If an abnormality is suspected at this point, a hysterosalpingogram should be done, provided there is no contraindication to it. Despite all this, the type of abnormality here reported has practically always been discovered accidentally or incidentally. Absolute conclusions cannot be drawn from the literature. The weight of opinion leans toward the belief that some of these patients show less tendency to become pregnant than normal women do, but that once they have become pregnant, that difference is no longer present. The type of operation, then, that seems indicated is the most conservative surgery consistent with the relief of the symptoms. Each case must of necessity be judged on its own merits; and, by virtue of the very nature of the anomaly described, no standard technic can be advocated. The patient in this case was relieved of her distressing symptoms and also was able to procreate after, as well as before, operation.

SUMMARY

A case of congenital anomaly of the pelvic adnexa is reported.

A brief review of the embryology of the female genital system is presented.

The literature on this condition is reviewed.

The cases of congenital anomaly of the adnexa that have been reported have been discovered accidentally or incidentally; the patients have been operated on for pelvic pain, for menorrhagia or metrorrhagia or both and in no two cases have the findings been identical.

Conservative treatment often relieves the symptoms and preserves the functions of menstruation and procreation.

PHYSIOTHERAPY IN RHEUMATOID ARTHRITIS*

WILLIAM A. ELLISTON, M.D.,† MARIE F. SILBER, R.P.T.T.,‡ AND DOROTHY GROVER, B.S.Ed., R.P.T.T.§

BOSTON

A RECENT health survey of chronic disease in a large cross-section of the population of this country by the United States Public Health Service|| shows that "rheumatism ranks first in prevalence, second both in producing chronic disability and in invalidity (permanent disability) and fourteenth in causing death." Rheumatoid arthritis causes a large proportion of this disability, and if untreated follows a relentless course.

The proper treatment of rheumatoid arthritis can and should be undertaken with optimism, but such treatment is of long duration and varies greatly with the individual patient. Physiotherapy is of paramount importance in all stages of the disease and is the leading factor in preventing chronic disability.

For ten years the physiotherapy program at the Robert B. Brigham Hospital has been continuously revised and improved on the basis of sound physiotherapy principles. Trial, then discard or inclusion, of countless procedures has resulted in our present methods; it is the purpose of this paper to present them.

POSTURE TRAINING

Training in body mechanics is of primary importance so that patients may develop a kinesthetic sense and form good postural habits. Faulty body mechanics produces undue strain, with resulting tendency to deformity of the joints, as well as disturbances in the respiratory, circulatory and digestive systems. If this condition is not corrected, it may contribute to a recurrence of joint symptoms due to strain and incorrect use, especially

in the lower extremities when weight-bearing is resumed.

Positions

In conjunction with training in posture, patients are placed in a hyperextended position for half-hour periods after meals. A pillow is placed under the dorsal spine and another under the knees, and the arms are extended over the head in a restful position. This brings about, as nearly as possible, the ideal weight-bearing posture, even though the patient may be forced to remain supine. Often there are patients who, because of marked kyphosis, must begin taking these positions without a pillow under the spine. No final statement can be made, therefore, as to the exact position during hyperextension and postural exercises, since adjustments must be made according to the deformities present in each case.

Exercises

Postural exercises in the supine position are explained as soon as patients are admitted to the hospital. They begin with the teaching of the correct use of the body, and the ability to maintain a position of rest without strain; for rest, in the best physiologic position, is an essential aid to recovery. The patients lie on their backs with the cervical spine extended and the arms, with elbows flexed, abducted to as near 90° as possible. This allows for a better chest position during the exercises. For teaching purposes we have found it beneficial for the physiotherapist to indicate to the patient with her hands where the muscle activity should take place. This eliminates repeated explanations and aids the patient in developing muscle sense.

||*The Magnitude of the Chronic Disease Problem in the United States*. 19 pp. National Health Survey No. 6. Washington, D. C., National Institute of Health, 1939. P. 2.

The first postural exercise is one of simple breathing, concentrating on an expansion of the upper chest as the air is taken in. At the same time the abdominal muscles must be kept contracted to eliminate abdominal breathing. This contraction is held until the air is expelled. In the second exercise the patient is taught to localize the breathing in the middle and lower chest. He inhales as in the previous exercise, contracts the abdominal muscles and maintains the lift of the upper chest while taking series of breaths at the region of the diaphragm, thus causing a lateral spread of the lower ribs. We do not advise advancing a patient to this exercise until he has thoroughly mastered the first one. The third exercise is the so-called "rib stretch." Normal breathing is resumed, the chest is kept in a relaxed position, and the abdominal muscles are slightly contracted to keep the pelvis stable as the patient attempts to elevate the ribs, alternately to the right and left. The value of this exercise is lost if lateral flexion of the dorsal spine or elevation of the shoulders takes place. The fourth and last exercise is the so-called "pelvic tilt." Breathing is continued at a normal rate with the chest in a relaxed position. The abdominal muscles are contracted without causing tension on the thoracic muscles. Simultaneously the patient contracts the gluteal muscles, attempting to flatten the back against the bed. These exercises can be continued even when the extremities are immobilized.

Following a period of complete bed rest, these exercises are repeated with the patient sitting on the side of the bed. This procedure teaches control of muscles against gravity and serves as a transition from the lying to the standing exercises.

To perform these exercises standing, the patient assumes a position with his back against the wall. The heels should be 4 inches away from the wall, hips and shoulders touching and chin in. When the patient learns to balance the body correctly without support, the final stage of posture training is reached: that of the proper mechanics of walking. This is a new procedure for arthritic patients who have not walked for a long time, and it therefore requires careful and prolonged supervision.

The exercises are supervised twice a week by the physiotherapists, and the patients are instructed to repeat them three times daily. Each exercise is done five times at first, and the number is gradually increased to a maximum of ten.

ACTIVE MUSCLE AND JOINT EXERCISES

Static Exercises

Before the joints are splinted during the acute

stage of the disease, it is essential that the patient be taught the value of keeping up muscular nutrition and tone through the medium of muscle-setting exercises, especially of the quadriceps and the gluteals. Since muscle setting does not involve joint motion, pain or damage to the joints is not increased. The patients are shown this method of exercise immediately following admission, and continue with it while confined to solid casts or until the acute condition within the joints has subsided. We cannot stress enough the importance of obtaining the full co-operation and understanding of the patients in this matter. Without the strength maintained through repeated muscle-setting exercises, it is more difficult to progress to exercises involving joint motion.

Free Exercises

Joint exercises should be begun as soon as any degree of painless motion is possible. They are aimed at securing increased flexibility of the joints and improving muscle strength. All exercises for the extremities are done in the lying position, since thus a minimum of effort is required. The motion should be confined so far as possible to one joint of the arm or leg.

Shoulder. The tendency of the arthritic patient is to use the entire shoulder girdle when exercising the arm; therefore we prefer bilateral performance in shoulder and elbow exercises. The pull of gravity is partially overcome if the elbows are kept in a flexed position while the shoulders are exercised in the anteroposterior and lateral planes. When muscle strength becomes sufficient to raise the arms with elbows extended, circumduction, beginning with a forward and upward pull, replaces the previous exercises. Free range of motion is permitted because fatigue and discouragement will arise if too much stress is put on the use of specific muscle groups to bring about the desired action.

Elbow. In exercising the elbow, the arthritic patient habitually eliminates supination and pronation. We have seen an increase in the tendency to subluxation in the elbow joint when these motions are not properly combined with flexion and extension.

Wrist and hand. Active exercises of the wrist and hand are seldom prescribed when ulnar deviation or flexion deformity is present, since it would be impossible for the patient to maintain a position beneficial for exercise. However, following manipulations when a corrected position has been obtained, flexion or extension exercises are taught as indicated by the degree of correction.

Hip. Owing to the inability of patients to lie

prone, hip-extension exercises are comparatively ineffective. We compensate for this by giving exercises in the hydrotherapy tank or by using elastic traction (Fig. 1). It is seldom necessary to in-

FIGURE 1.

struct patients in hip-flexion exercises because of the flexibility obtained from the position assumed at mealtimes and during recreation.

Knee. As a variation of the quadriceps-setting exercise, an attempt is made to lift the heel off the bed without raising the thigh. This exercise is possible only for those patients who are able to extend the knee fully. Knee extension against gravity is given as the strength in the quadriceps muscle increases and the patients become able to assume a sitting position. Performed in this way the common error of substituting hip flexion for quadriceps contraction is largely avoided.

Ankle and foot. To help in overcoming functional deformities in the foot, routine exercises are prescribed. Flexion and extension of the ankle are practiced for flexibility, and if performed slowly will aid in increasing muscle strength. The combined motions of plantar flexion, inversion and dorsal flexion, with emphasis on the inward and upward pull, are beneficial to the tarsal arch. When flexing the toes to improve the strength of the intrinsic muscles of the foot, the patient is told to maintain as great a degree of dorsal flexion of the ankle as possible.

During the patient's stay in the hospital, all active joint exercises are carried out three times daily. Each exercise is done only a few times at first, and the repetitions are gradually increased according to the muscle strength gained. The ex-

ercises are supervised by the physiotherapists twice a week, at the time when the postural exercises are checked.

Assisted Exercises

The improvement of patients with marked muscle atrophy is more rapid if they are assisted in some of their exercises. This applies particularly to leg exercises, which are simplified by the use of elastic traction. This consists of a wide, felt-lined canvas cuff suspended by a cable elastic from overhead frames. The cuff, which is placed just above the ankle, is sufficient to eliminate the friction of the bed in lateral hip motions and to offer enough resistance to overcome the pull of gravity in hip extension (Fig. 1). It may also be employed to encourage knee activity, when it should be placed just below the knee. Both legs are drawn up, and extension is attempted with each leg alternately; this is shown in Figure 2, in which only the right knee is flexed. Care must be taken that the hip is held stationary as the knee is extended; otherwise the patient may institute hip motion, which, modified by the elastic traction,

FIGURE 2.

will give flexion and extension of the knee without contraction of the quadriceps muscle.

Another method of aiding muscle function is by underwater exercise. Its value lies not only in the supporting action of the water and the relaxation gained through increased body warmth, but also in the encouragement given to the semihelpless patient.

Restricted Exercises

As active motion becomes freer, it is necessary to restrict undesired movement by supporting, in a

correct position, the part to be exercised, as, for example, by stabilizing the shoulder girdle while shoulder exercises are carried out. In treating elbows following operation for arthroplasty, it is essential to give the same type of assistance, holding down the shoulder as the elbow moves. Previous to an arthroplasty for relief of ankylosis in the elbow joint, the patient has been accustomed to using the arm as a whole, it is the duty of the physiotherapist to help him overcome this habit.

Before he can exercise the hand properly, it is necessary to eliminate deformities that can be corrected passively. The commonest of these are ulnar deviation and subluxation of the metacarpophalangeal joints. To maintain proper alignment of the bones, so that the maximum pull of the muscles may be obtained, pressure is exerted along the ulnar border and under the metacarpal heads. With this support the muscles contract to better advantage, or if subluxation is overcome, are restored to their normal course with a minimum of joint strain.

It is rarely necessary to stabilize the pelvis during this type of hip exercise. If the opposite leg can be abducted, the weight of the leg and pelvis is sufficient to hold the body so that motion occurs in the hip joint alone. An exception occurs in underwater exercises, in which the movement tends to be along the path of least resistance and the patient substitutes activity in the lumbar spine to compensate for the limited hip motion.

In those joints in which two muscle groups work simultaneously, support must be given to the moving part to stop motion of the undesired muscle group, for example, in abduction of the hip, rotation must be guarded against. Such lack of co-ordination is particularly evident following an arthroplasty or osteotomy.

Resisted Exercises

It is not usually our custom to offer resistance in joint exercises, owing to the tendency toward subluxation of the joints. Although such exercises are beneficial to the musculature, they are detrimental to a joint when its structure is impaired. Resistance to the exercises may be offered in cases in which a joint has been only mildly involved and there is, except for muscle atrophy, a complete return of function.

FORCED MOTION

Joint Stretching

Regardless of the amount of active exercise that a patient can perform, the range of free motion in a joint is limited by adhesions and contrac-

tures. Therefore, when the disease becomes quiescent and the joint symptoms subside, it is necessary to stretch the fibrous adhesions. A standardized procedure is essential in order that the patient may know what to expect. The process is at best painful, and increased spasm and contracture, due to fear, must be avoided. As patients become accustomed to one method of treatment they become less apprehensive and can concentrate on relaxing. Traction must be applied when stretching arthritic joints, to relieve friction within the joints and to avoid the possibility of fracture. The patient's tolerance will not permit more than three or four stretchings at a time in any one direction. Pain is lessened if a few strokes of massage are interspersed with the exercises. The process should seldom be repeated more than three times a week, except for the postoperative cases, which should be treated daily. If increased stiffness results and constant pain persists, treatment should be discontinued.

Shoulder The first consideration in exercising the shoulder is stabilization of the acromioclavicular joint. The physiotherapist places one hand firmly over this articulation, but in a position that will not interfere with the larger tubercle of the humerus, the other hand is placed over the posterior aspect of the humerus a few inches below the glenoid. At the termination of the arc of active motion, it is necessary for the patient to relax completely, so that traction may be applied at this point, it must be maintained throughout the stretching process. Care should be taken to equalize the force between the downward pressure on the shoulder girdle and the upward lift of the humerus. We cannot specify the degree of increased motion that can be obtained, since this will vary with individual cases and according to the amount of destruction within the joint. Flexion and extension must take place in the direct anteroposterior plane, with precautions against rotation of the humerus. If the rest of the arm is involved, support should be given to the elbow and wrist. To eliminate all strain the stretching process must be confined to one articulation at a time. Abduction may be assisted in the same manner without altering the position of either the patient or the physiotherapist. The motion must not be carried beyond the 90° angle, because motion above that point will involve the whole shoulder girdle. Owing to the possibility of fracturing the surgical neck of the humerus, stretching in inward and outward rotation is not advisable unless the patient can abduct the arm to shoulder level. In such cases the elbow is flexed to a right angle, and

traction is applied to the humerus. With the traction held firmly there will be no elevation of the shoulder girdle; this eliminates the necessity of holding down the acromioclavicular articulation. The traction can be maintained and at the same time pressure exerted on the forearm, stretching the shoulder in inward and outward rotation (Fig. 3). It usually follows that adhesions

FIGURE 3.

are no longer present when the shoulder can be fully rotated outward, that is, the arm placed in the aforementioned position with the dorsal surface of the hand and the entire forearm in contact with the bed.

Elbow. For stretching the elbow joint the arm is brought in close to the side. To avoid pressure of the elbow against the bed, the physiotherapist places one hand under the arm and in this position firmly grasps the humerus at the level of the condyles; the other hand, which will supply the traction, grasps the forearm near the joint. This traction must be applied equally on both radius and ulnar, for an unequal pull will so affect the alignment of the bones that injury to both elbow and wrist may result. Supination is attempted simultaneously with flexion. When stretching in the combined motions of extension and pronation, if limitation is slight it is well to change the hold on the forearm to an overhand grasp; this releases pressure on the muscles and eliminates pinching of the skin. Relaxation of the shoulder must be maintained throughout this procedure, since there is a tendency to compensate for lack of elbow extension by raising the shoulder joint.

Wrist and hand. Adequate traction is difficult to apply in the wrist, owing to the arrangement of the carpal bones. The factors for consideration are an increase in the flexibility of the joints and the stretching of the carpo-ulnaris muscles. This is best accomplished by placing the supporting hand just above the wrist against the radial border of the forearm and the stretching hand just be-

low the wrist against the ulnar border of the hand, with the fingers around the parts parallel to the wrist joint. Because of the disagreeable sensation caused, it is well not to exert extreme pressure over the radial artery.

The metacarpophalangeal joints should be stretched individually. Pressure is exerted on the palmar surface of each metacarpal head to restrict motion in the carpometacarpal junction. Traction is maintained on the adjacent proximal phalanx, with the fingers holding the lateral aspect, close to the joint. This position allows for free movement of the tendons that cross the dorsal and palmar surfaces of the articulations. All interphalangeal joints are stretched in like manner. It is of the utmost importance that these small joints be stretched with a short leverage, since there is constant danger of fracture, owing to the bone atrophy so often present.

Hip. Satisfactory stretching of the hip joint cannot be executed by one physiotherapist alone. The pelvis must be stabilized bilaterally to provide countertraction to offset the amount of traction applied. The lower leg should be supported, and all traction must be applied above the knee. This requires the combined efforts of two physiotherapists; one stabilizes the pelvis, while the other applies the traction, assists with the motion and at the same time eliminates rotation of the femur. This technic is particularly valuable following arthroplasties of the hip, and should be carried out daily over an extended period of time. Following surgical operations on the hip joint, patients are able to do muscle-setting exercises, but because of the weight of the femur and the temporary damage to muscle fibers, active motion is slow to return. Therefore, to maintain mobility of the hip joint, assistance must be given. As pain and muscle spasm subside, motion may be increased by careful stretching. When weight bearing is resumed, there is a tendency toward contraction of the tissues that necessitates an increase in the amount of traction as the joint is stretched.

Knee. This joint is extremely susceptible to damage if stretched improperly. Its structure is such that subluxation may easily occur or increase unless a short leverage is used with traction equally distributed on the tibia and fibula, avoiding outward rotation. Of relative importance in stretching the knee is the position of the hip joint. In stretching a flexion deformity no motion should occur in the hip. Therefore, the hip must remain semiflexed throughout the process. The hand supplying the traction on the lower leg exerts pressure upward under the calf. The other hand, placed over the femoral condyles, exerts downward force to equalize the pressure and steady the femur.

When marked flexion deformity is present, every effort is made to reduce posterior subluxation of the tibia as well as to decrease the angle of deformity. During the process of stretching, constant attention is given to hold the improved alignment of the bones while an increase in the mobility of the joint is attempted. Following operative procedures or extensive treatment in solid casts, it may be necessary to assist patients to regain flexion of the knee. It must be borne in mind that the end result should include ability to perform complete extension while retaining as much power of flexion as possible. If the hip can be flexed, a more effective stretching in knee flexion can be accomplished, with less risk to the femur owing to relaxation of the rectus femoris muscle. We believe that this undesired position of hip flexion is held so briefly that it is offset by the gain to the knee.

Ankle and foot. Owing to the general structure of the ankle, it is unwise to apply traction when giving assistive exercises, since too much strain on the ligaments results. The ankle may be forced in either plantar or dorsal flexion according to the deformity present, and so far as possible eversion should be eliminated. The latter position is often associated with peroneal spasm, so that stretching should be used as a preliminary to immobilization in casts. Limitation of motion in the tarsometatarsal joints is usually present with the common deformity of valgus. This deformity requires careful and selective stretching in inversion, with the foot supported in a neutral position.

The metatarsophalangeal joints are stretched in flexion with a technic identical to that used on the corresponding joints of the hand. The foot is held in dorsiflexion and ample support is given under the metatarsal heads, while each toe is stretched separately. If hallux-valgus deformity is present it will cause considerable disorganization of the metatarsophalangeal joints. Therefore, stress must be placed on correct alignment of the bones during the stretching process.

The force of gravity may sometimes be used to help increase joint motion, although it is seldom sufficient to overcome the strength of muscle spasm or the adhesions present. However, in some cases gravity can be used to help patients increase the flexibility of their own joints, for example, dangling their legs over the side of the bed to regain knee flexion.

Manipulation

This method of forced motion is classified as a surgical procedure. Joints are manipulated.

anesthesia by the surgeon and returned to
improved position, and the patient returned
mediately returned to position of the
hesions.

Passive Movement

The use of passive movement in the treatment of rheumatoid arthritis is limited. It could be well if joints in the active stage of arthritis were put through their full range of passive motion every day. However, if patients are unable to perform any active motion without pain, they usually experience pain at the end of an attempt at passive movement, and this may lead to an increase in pain.

contains few reports of cases in which endometrial cysts of the undevolved size reported in subjects. In this, a statement by [unclear] says, "... that adenocarcinoma is an increased growth of the endometrium, that it does not

a marked hyperemia and aids in the reduction of pain.

FOLLOW-UP PROCEDURE

Although not a form of treatment, photography for record purposes is an important part of our follow-up work. This procedure is undertaken by the Department of Physical Therapy. Photographs are taken of all patients on admission, previous to and following operations, and at varying intervals when they return to the clinic. These photographs consist of anterior, posterior and lateral views of the standing position of ambulatory patients and of views of the characteristic lying position of nonambulatory patients. Photography of visible deformities and composite pictures showing limited joint motion are of great value in following the patients' progress.

Following discharge from the hospital continued encouragement and supervision are given to these arthritic patients under the direction of the Home Service Department. Arrangements are made for patients to attend home-service clinics, and a complete survey is made of all outlined treatments that the patients have been directed to follow at home. The physiotherapist reviews all exercises and makes necessary corrections or additions.

SUMMARY

The program of physiotherapy for arthritic patients now in use at the Robert B. Brigham Hospital is discussed. Details of the technics used are given from the viewpoint of a physician-in-charge, working with an experienced physiotherapist.

PEDUNCULATED ENDOMETRIAL CYST OF THE UTERUS

Report of a Case

ALEXANDER A. LEVI, M.D.*

BOSTON

IN THE case reported herein, a pedunculated endometrial cyst of the endometrium, 3.5 cm. in diameter, was removed at operation. Such a cyst is rarely seen by pathologists or surgeons, so that its discovery aroused considerable comment. This paper is therefore intended chiefly as a case report, but it also draws attention to the variety of pathologic changes which may involve the pelvic organs at the same time.

The patient was operated on twice, the procedure employed during the second operation being governed by the pathologic findings at the first.

CASE REPORT

S. G., a 39-year-old woman, was first examined by me on September 16, 1939. She had been married for 21 years and had had three pregnancies, the oldest child being 19 and the youngest 13. There had been no miscarriages. The menses began at the age of 13 and occurred regularly every 28 days, lasting for 5 days. Two previous operations had been performed, a hemorrhoidectomy at the Boston City Hospital in 1936, and a dilatation and curettage, a Kelly advancement operation and anterior and posterior colporrhaphy at the Beth Israel Hospital on October 21, 1938. Following the latter operation an intravenous pyelogram was taken because of urinary complications. During this procedure a dermoid cyst of the left ovary was diagnosed.

The patient stated that since the last operation she had had pain in the left lower abdomen; her menses had been regular, and accompanied by severe pain just before and during each period. The last period had occurred on August 25. There was severe flow, and large clots were passed. Three weeks later the severe flow recurred. The

bleeding continued actively, including the day on which examination was performed.

Examination showed the uterus to be in a normal position, about one third larger than normal, and tender. A hard mass, presumably a fibroid, half the size of a golf ball could be palpated in the right uterine wall above the cervicofundal junction. The right vault was normal. The left contained a movable tumor mass—the dermoid cyst—10 cm. in diameter. The cervix was dilated, and a tumor mass 4 cm. in diameter projected partially through the external os. It was reddish blue and firm. Blood flowed profusely about it and out of the cervix.

The patient was operated on by me at the Evangeline Booth Hospital on September 17. At preoperative examination, under general anesthesia, the cervix admitted three or four fingers. On exploration with the finger a long pedicle was discovered coursing from the top of the intracervical tumor mass to its point of attachment, high in the uterine cavity on the right. The mass was dissected manually; the pedicle was cut at its base and the mass was removed intact. The uterine cavity was then curetted. A moderate amount of curettings was obtained.

Pathological examination of the tissues was performed at Tufts College Medical School by Dr. H. E. MacMahon. The report reads as follows:

Specimen A consists grossly of a piece of tissue, circular, flat and measuring 2.5 by 2.0 by 0.3 cm. One surface is pigmented and granular, the other is rough and dissected microscopically. This is a strip of endometrial tissue with underlying myometrial smooth muscle. The endometrium shows a few glands surrounded by little or no stroma extending into the underlying muscle.

Specimen B consists of a globular mass 3.5 cm. in diameter, fluctuant and opaque. One surface is bare and dissected and in this area the wall is thin. A larger area is covered by a layer of dense, opaque, bloodstained, skinlike tissue. Section of the mass

*Instructor, Department of Obstetrics, and teaching assistant, Department of Gynecology, Tufts College Medical School; senior visiting obstetrician, Evangeline Booth Maternity Hospital.

shows a smooth-walled cyst varying from 0.1 to 0.4 cm. in thickness and filled with chocolate-colored fluid. Microscopically, the cyst is lined by flattened, compressed and atrophic endometrium, composed of a single layer of flattened epithelial cells and a narrow zone of endometrial stroma. There is a layer of flattened atrophic muscle lateral to the stroma, and the outer surface is bordered by endometrium.

Diagnosis: pedunculated endometrial cyst of the uterus, showing no evidence of malignancy.

Note. I should consider these findings consistent with an endometrial cyst that has enlarged and filled the endometrial cavity like a polyp. The presence of the smooth muscle bordering the cyst indicates that it has originated in the myometrium rather than in the endometrium, as was suggested in the gross diagnosis.

The accompanying photographs (Figs. 1 and 2) demonstrate the size and structure of the cyst.

Although it was known at this time that an intramural fibroid tumor and dermoid cyst of the left ovary were

FIGURE 1. *Pedunculated Endometrial Cyst of the Uterus.*

present, abdominal surgery was not done. The patient's condition was unsatisfactory, as a result of the marked blood loss which she had suffered prior to this operation. Furthermore, it seemed unwise to subject her to an abdominal operation when it was known that she had had a dilated cervix for an indefinite period of time.

On January 4, 1940, I again operated on the patient at the Evangeline Booth Hospital. The operation, performed in two stages, consisted of dilatation, curettage and perineorrhaphy, and supravaginal hysterectomy and bilateral salpingo-oophorectomy.

During the curettage it was noted that the endometrial tissue was extremely thick and more abundant than usual. Because of this finding and the previous pathological diagnosis, I felt justified in making a diagnosis of endometriosis of the uterine wall. With this background and the knowledge of the existence of a large dermoid cyst on the left side, I decided to remove the right ovary as well. The pathological report of the tissues removed at this operation and examined at Tufts College Medical School by Dr. James M. McFadden reads as follows:

The specimen consists of the body of a uterus measuring 6 by 7 by 4 cm. with the left tube and ovary attached. There is a 1.5-cm. laceration on the superior surface of the fundus, apparently rendered at time of removal. There is a firm leiomyoma about 2 cm. in diameter, with a firm, cut surface and sworled appearance, in the right aspect of the cervix. Also there are small grayish brown spots measuring up to 2 mm. in

diameter, located anteriorly to the uterine cavity and slightly to the right of the midline. These are consistent in gross appearance with endometriosis. The endometrium measures approximately 3 mm. in thickness. It is soft and gray with a bloodstained surface.

The fallopian tube is slender and measures 7.0 by 0.6 cm., and is stretched over the surface of a large ovarian cyst measuring 7.5 by 7.0 by 5.5 cm. Upon sectioning the ovarian cyst, the wall is seen to be thin, with a rough inner surface and a moderate growth of hair. The cavity is filled with a sticky, yellowish-gray, sebaceous-like material. There is a ridge on the inner surface measuring 1.5 by 1.0 cm. Sections of this ridge reveal a moderately firm, grayish-white, smooth, cut surface. Close by is a small hard area, and when it is opened two teeth of the incisor pattern are found, completely imbedded in the cyst wall. Also at one pole there is a corpus luteum 2 cm. in diameter.

The additional specimen consists of a free tube and ovary. The tube is small and has a normal gross appearance. The ovary measures 4 cm. in diameter, and section reveals numerous small follicular cysts and a corpus luteum. There are small hydatid cysts on the surface of the tube.

Microscopically, the sections of the dermoid cyst show the thin portion to be lined by stratified squamous epithelium. Sections through the ridge show this epithelium covering a mass of mucous glands. Also there is a small strip of cartilage present, some smooth

FIGURE 2. *Pedunculated Endometrial Cyst of the Uterus.*

muscle, and hollow structures lined by pseudo-stratified ciliated epithelium, similar in appearance to the respiratory type. The corpus luteum is noted. Sections of the uterine wall prove the small brown spots noted grossly to be endometrial islands. The leiomyoma is noted. The endometrium is in the early lutein phase. The fallopian tube is scarred. There is no evidence of malignancy.

Diagnosis: dermoid cyst of the ovary; corpus luteum and follicular cysts of the ovary; leiomyoma of the uterine cervix; endometriosis of the uterus (endometrium in early lutein phase).

The literature contains few reports of cases in which pedunculated endometrial cysts of the endometrium have developed to the size reported in this paper. To substantiate this, a statement by Novak¹ is offered. He says, "... that adenomyosis represents merely an increased growth activity of otherwise normal tissues, that it does not

assume the circumscribed form so characteristic of genuine neoplasms. . . ."

Changes representative of endometriosis less often involve the uterus. They are most frequently found in the pelvis or abdomen. Crile² writes:

Endometriosis is defined as the presence of endometrial tissue in ectopic locations. . . . Endometrial tissue may be implanted on the ovary, on the pelvic peritoneum, in the umbilicus, in the rectovaginal septum or in the laparotomy scars. It functions as endometrium, undergoing the cyclic changes of menstruation. It is, therefore, capable of forming cysts of retained blood (chocolate cysts) and of producing pain at the time of menstruation. . . . It is interesting to note that more than 24 per cent of 37 patients in this series had fibroids of the uterus, endometriosis and menorrhagia. This association has been noted in other series of cases and cannot fail to suggest that there may be an underlying endocrine factor which could well be responsible for all three conditions.

This statement is quoted because it focuses attention on the variety of pelvic disease found in this case.

As to the rarity of such cysts, Masson³ reports a study on the situations of adenomyomas found at operations performed from 1923 through 1934, in-

clusive. A total of 576 patients were operated on, but not one case disclosed the presence of a pedunculated endometrial cyst similar to that reported in this paper.

SUMMARY

A case is reported of a thirty-nine-year-old woman in whom the following were found at the same time: a pedunculated endometrial cyst of the uterus, endometriosis of the uterine wall, an intramural fibroid and a dermoid cyst of the ovary.

In spite of the presence of multiple pathologic entities in the pelvis, almost no unusual changes occurred in the menstrual cycle.

Although endometriosis of the uterine wall is not rare, large endometrial cysts of the uterus are uncommon.

MEDICAL PROGRESS

ABDOMINAL SURGERY

ARTHUR W. ALLEN, M.D.*

BOSTON

DURING the past year many outstanding contributions have been made in the field of abdominal surgery. Some of the timeliest and most useful subjects are recorded.

ANESTHESIA

Bartlett³ has described in detail a useful method of anesthesia for upper abdominal surgery. This consists in blocking the intercostal nerves from the seventh through the eleventh in the midaxillary line on both sides with 2 per cent novocain. He recommends that this be accomplished under light nitrous oxide and oxygen inhalation, which may be continued throughout the operation. Ten minutes is necessary to obtain the full effect of the novocain. This method has been used at the Massachusetts General Hospital in gastric as well as biliary-tract surgery with considerable satisfaction. Evipal or a similar preparation given intravenously can be substituted for nitrous oxide and oxygen. Splanchnic block by Ogilvie's² method added to intercostal block is helpful. Subcostal or transverse incisions are more easily closed when this type of anesthesia is used, although added relaxation of the abdominal wall can be obtained by novocain infiltration into the rectus sheaths.

WOUND HEALING

Whipple⁴ selected the subject of the critical latent or lag period in the healing of wounds for his presidential address before the American Surgical Association at its annual meeting in 1940. He discusses the local and systemic conditions pertaining to wound healing. The local factors are the amount of killed or damaged tissue in wound surfaces, the vascularity of the tissues involved, the integrity of blood flow to the damaged tissue, the amount and character of the exudate in the wound space, the number and character of infectious organisms present and the number and character of foreign bodies to be extruded or encapsulated. The systemic factors are the age of the tissues (whether they are adolescent, normal adult, or senescent and degenerated), the state of hydration,

nutritional balance, vitamin balance and the state of the general circulation and blood.

He describes the lag period as being that time between the receipt of the wound and the beginning of tensile strength between the approximated structures. Local factors are mainly the responsibility of the surgeon at the time of operation; they are sharp dissection, careful hemostasis, gentleness of touch, careful protection of the wound and the use of fine nonabsorbable suture material. The systemic factors are dealt with beforehand as much as possible, and this is continued during the convalescent period.

Coller and Valk⁴ present a logical revival of the delayed closure of infected wounds. They recommend that the fat and skin be loosely packed open with acriflavin gauze, and that sutures be placed at the time of operation and tied on removal of the gauze twenty-four hours later. This is particularly adaptable to wounds made in the closure of colostomies, fecal fistulas and perforated appendices. The results are superior to those in wounds closed partially over drains of one sort or another. I have used their suggestion extensively with great satisfaction, and have found that iodoform gauze is fully as effective as acriflavin gauze. In some cases it is wise to use a small dose of Pentothal Sodium intravenously when tying the final sutures.

Cutler and Dunphy⁵ present experimental and clinical evidence that fine silk in the closure of infected wounds is far superior to catgut. The amount of silk discharged from such a wound is no greater than in clean wounds. Hernia in the scar very rarely occurs when silk has been used, whereas it is a frequent sequel to infection when the wound had been closed with catgut. In frankly infected wounds, such as occur during operations for suppurative appendicitis, the layers of the abdominal wall are built up with interrupted fine silk sutures, but the skin itself is not closed. It occurred to Kelly⁶ that the skin of such a wound might be safely closed at a later date, according to Coller's suggestion.

Meade and Ochsner⁷ present excellent experimental and clinical evidence that cotton thread has all the advantages of silk in the repair of wounds, and in some respects other than its low cost is superior.

*Lecturer in surgery, Harvard Medical School, chief of the East Surgical Service, Massachusetts General Hospital.

PENETRATING WOUNDS OF THE ABDOMEN

Two excellent presentations on penetrating wounds of the abdomen have come forth during the past year, those by Storck⁸ and Rippy.⁹ Both these authors analyzed the wounds according to severity, the viscera injured, the number of perforations, the age, sex and color of the patient and the time interval between injury and operation. The mortality is quite high, approximately 33 per cent. Early operation, performed as soon as shock can be combated, is recommended in all cases save shotgun wounds sustained at some distance from the weapon. Blood and plasma banks, better transportation facilities and the use of sulfanilamide, it is prophesied, will reduce mortality.

HERNIA

Warvi and Orr¹⁰ review the literature on hernia, discuss the embryology and anatomy and report a case of supravescical hernia. This is one of the infrequent causes of acute intestinal obstruction. The authors believe that hernia of the intestine in and about the urinary bladder is commoner than is usually thought, and suggest having this in mind when dealing with small-bowel obstruction.

Rienhoff¹¹ offers a modification of the Halsted "second" operation for inguinal hernia. He maintains that recurrence often takes place in the lower or critical angle of the wound, since structures in this area are prone to contain little or no fascia that can be easily approximated. This has been recognized by many surgeons, and various ways of correcting it have been offered. Rienhoff elevates the external oblique fascia to uncover as much of the lower rectus sheath as possible; then a longitudinal incision is made through the rectus fascia near the midline. He asserts that this allows the lower edge of the fascia, which is contiguous with the internal oblique, to be sutured to Poupart's ligament without tension. The cord is undisturbed and the cremaster utilized in the manner described in Halsted's second and finally adopted operation.

APPENDICITIS

Ravdin, Rhoads and Lockwood¹² report on a series of patients with appendiceal peritonitis treated by operation and sulfanilamide by hypodermoclysis. They have demonstrated experimentally that the drug reaches the blood level in the peritoneal fluid very quickly. They admit that their series is yet too small for accurate conclusions, but in comparison with a previous series of patients treated in the same clinic, one is impressed by the possibilities of the newer method. Delayed operation for better localization was used in approximately

2 per cent of cases. Wound drainage was used in 38 per cent of cases. Wangenstein-Paine suction was used routinely until there was active peristalsis and free passage of gas from the bowels. Sulfanilamide therapy was continued from five to seven days postoperatively. The mortality in the previous group of 552 patients was 1.4 per cent, whereas in 257 similar cases treated by the addition of sulfanilamide it was 0.4 per cent.

Barrow and Ochsner¹³ have collected statistical data indicating that the mortality rate in appendicitis is not rising, as has been frequently stated, but is actually decreasing. They attribute this fact to a better understanding and management of appendiceal peritonitis.

ULCERS OF THE STOMACH AND DUODENUM

Contributions continue with considerable profusion on the subject of ulcers of the stomach and duodenum. That ulcerative lesions of the stomach must be considered malignant until proved benign is a dictum that is gaining favor. Such patients are being more carefully followed and subjected to surgery, unless rapid and complete healing can be demonstrated radiologically or by the gastroscope. Physicians are no longer misguided by the frequent improvement of symptoms and the early decrease in the size of the crater when palliative measures are tried. Increasing numbers of patients are benefited by early resection, while the carcinoma is still in situ and therefore curable. Patients developing first symptoms after middle life who have a gastric ulceration are so likely to have a malignant lesion that little time should be wasted on palliative treatment.

Subtotal gastrectomy for duodenal ulcer is giving a high percentage of patients who continue to be symptom free. The operative mortality for such procedures is now very low in the hands of men experienced in this field. Walters¹⁴ and McClure and Fallis¹⁵ reported their experiences during the past year.

The amount of stomach removed in square centimeters has also interested Wangenstein et al.¹⁶ Their analysis concerning the permanent lowering of the gastric acidity following various surgical procedures is interesting but not too convincing, especially in regard to the Finsterer exclusion procedure. Many surgeons have been faced with stomal ulcers following this operation, and believe that the antrum should never be left in situ unless the mucosa has been removed. I am not too pleased with it even so, since, although the acid-activating hormone may be removed by eliminating the mucosa, a poor structure to close is left. Two nonfatal leakages have occurred in my own series

of such operations, and for this reason I believe that extirpation of the antral segment with as much of the fundus as possible should be done whenever possible.

Zollinger¹⁷ suggests a plan for radical fundus-sectomy, particularly when dealing with secondary ulcerations. His operation is well conceived, and on occasion may be of value. Simpler methods, however, seem adequate, provided an effort is really made to include a large segment of the fundus in routine subtotal gastrectomy.

More awareness of the hazard of massive hemorrhage from gastric and duodenal ulcer is apparent. Hinton and Maier¹⁸ believe that the chronicity of the ulcer is a better explanation of fatal bleeding than is the age of the patient. At the Massachusetts General Hospital, we¹⁹ analyzed our own cases on the basis of all factors, including duration of symptoms, and were disappointed that our preconceived idea of chronicity was not evident in the fatal group. The dividing line of approximately fifty years of age between those who spontaneously recovered and those who died was an unexpected finding. It has held true in our clinic, and we have been able to rescue 8 patients with duodenal and 3 with gastric ulcerations above the age of forty-eight from acute massive hemorrhage by early radical operation; during this time none below this age have bled to death on conservative treatment. The fact that Hinton and Maier¹⁸ have been able to obtain a better history and thus interpret their findings on the basis of a long standing callous ulcer is of additional importance, and suggests another way of selecting the proper patient for operation. Wangenstein²⁰ believes that the age or chronicity factors are not so vital as the stage of shock produced by the hemorrhage. If profound shock occurs, it should be combated and radical operation undertaken. I doubt the soundness of this policy, since we have seen many patients in the most profound shock, even with repeated episodes over a period of several days, recover. Those with elastic blood vessels will make a recovery so that operation can be undertaken at an optimum time of election. One may argue that the mortality in modern gastrectomy is so low that one need not worry about those who may die or recover from hemorrhage, and may advocate early operation on them all, as does Finsterer.²¹ Economically, this is sound. In practice, however, when large groups of statistics are available the added risk during acute hemorrhage in the young patient is unjustifiable. Graham, Horsley, Hinton and Clute in an unpublished panel discussion on "Acute Massive Hemorrhage from Peptic Ulcer" agreed on many important points.

First, conservative management of most patients during the acute phase is the correct method of treatment. Second, operation, if undertaken, should be a radical procedure with ligation of the vessels supplying the ulcer area; this should be done early before depletion of the tissues has taken place or not at all. Third, the occasion for such a procedure is rare, but if well conceived at the right time and on the right patient, a rescue may be made. Fourth, early feeding is reasonable, but the patient must desire the food and not be forced to take it. Fifth, feedings may be of any type so long as the food is finely divided and smooth.

RARE TUMORS OF THE ABDOMEN

Lahey and Colcock²² have reported on 7 cases of leiomyoma and leiomyosarcoma of the stomach treated in the Lahey Clinic. Five of their cases showed sarcomatous degeneration, and for this reason they advocate radical resection rather than local removal of the tumor. One of their cases required total gastrectomy. The tendency for such lesions to bleed profusely is well known, the first symptom being that of massive hemorrhage. Often the lesions are mistaken for inoperable carcinoma. Many of these tumors are quite benign, but the determination of this point cannot be made until the sections have been studied.

Ransom and Kay²³ call attention to the frequency of tumors of neurogenic origin commonly supposed to be leiomyomas, and report 9 cases with such tumors of the stomach encountered in a total group of 18 cases with neurogenic tumors of the abdomen. Radical surgery, they hold, is indicated when possible in this type of tumor, since many of them are sarcomatous. The results have justified this radical attitude. Morton²⁴ calls attention to a very large tumor of this nature that was reduced to an operable state by previous radiation. Miller²⁵ has had a similar experience with postoperative radiation in a large neurogenic sarcoma involving the bladder.

CARCINOMA OF THE STOMACH

There is a gradual awakening among the profession to the terrific toll of human life taken by carcinoma of the stomach. Probably not less than 30,000 deaths occur every year in the United States from this cause. It is gratifying to learn that Surgeon General Parran plans an educational campaign on this subject in the near future. So far, the etiology is unknown. Some cases appear to develop from a benign ulcer, but proof of this is hard to establish. Early diagnosis followed by immediate operation is the only way to improve the very discouraging cure rate. At present, on all

figures available for follow-up studies, the percentage of five-year cures in cancer of the stomach is approximately 5. It is discouraging to the surgeon to be able to rescue so few patients admitted to the hospital with this diagnosis. Palliative resections are justifiable whenever possible, since many of these patients have a respite of two or three years.

The most valuable measures to improve the situation are as follows. Every ulcerating lesion of the stomach must be considered malignant until proved benign; this means constant supervision until the ulcer is completely healed and remains healed by follow-up examinations. Symptoms of stomach disorders beginning after the age of forty must be considered to be due to cancer of the stomach until proved otherwise; symptoms and physical examination must be carefully evaluated; gastric analysis, x-ray studies and gastroscopy must all be employed in an effort to find the lesion. Ulceration of the stomach manifesting itself for the first time and without previous symptoms after the age of forty is so likely to prove malignant that palliative treatment should be of very short duration or entirely abandoned in favor of early radical surgery. The laity must become conscious of this danger and must be warned against delay in reporting their symptoms to their physicians. Legislation should be sought to limit the advertising of remedies for indigestion, particularly over the radio.

Contributions to the technic of gastrectomy for carcinoma are as follows. Wangenstein²⁶ demonstrates a feasible aseptic gastric resection for subtotal gastrectomy. This is particularly applicable to the achlorhydric stomach involved with a localized infected carcinoma. Smithwick²⁷ has developed an aseptic technic applicable to total as well as subtotal gastrectomy and colectomy. This is based on the production of a firm char of healthy tissue over a broad clamp with a slow cautery. A basting stitch is placed through the eschar, and the anastomosis made without danger of leakage. It is possible that the use of some such chemical as sulfanilguanidine²⁸ may eliminate most of the danger of infection during operations on the gastrointestinal tract. This drug is said to be absorbed poorly by the host and to rid the tract of infectious organisms in a short time when administered by mouth.

Graham²⁹ has published his results with total gastrectomy for advanced carcinoma. Owing to difficulty with leakage at the esophagojejunal anastomosis by the usual methods, he suggests a modification that encloses the lower end of the esophagus in the loop of jejunum. This is done in such a manner as to bring a very broad surface of the

serosa of the jejunum in contact with the external layers of the esophagus. The jejunal loop is also carefully suspended from the diaphragm. Total gastrectomies for extensive cancer have been performed in more than 50 cases by the staff of the Massachusetts General Hospital. The procedure is now well standardized, and the immediate results are excellent.

DUODENAL DIVERTICULA

Morton³⁰ has collected the surgical literature on duodenal diverticula and summarizes the operations in 49 cases reported since 1915. He adds 2 cases operated on in the University of Rochester Clinic, commenting on the fact that the diagnosis of primary diverticulosis of the duodenum had been made in that clinic in at least 33 cases. This emphasizes the frequency of the lesion itself, but the rareness for the need of a surgical attack on it. He points out that surgery is indicated for the following reasons: mechanical—giving rise to symptoms from local stasis in the diverticulum or from partial obstruction to the biliary tract, pancreatic ducts or duodenum; inflammatory—local diverticulitis, perforation, abscess and peritonitis or secondary inflammation of the biliary tract (jaundice), pancreas, duodenum and retroperitoneal tissues; and neoplastic changes. The results in all reported cases were at least 80 per cent successful. In 8 cases no follow-up was given. In 6 per cent the symptoms were not relieved. The mortality rate was 6 per cent.

ULCERATIVE COLITIS

Cave³¹ in a review of his experience with ulcerative colitis describes in detail his present method of performing permanent ileostomy. This leaves the proximal end of the ileum in the right lower quadrant, brought out through a modified McBurney incision. The distal segment, which becomes a mucous fistula, is brought out through a stab wound to the left of the midline just below the umbilicus. Cave says that this reduces the complications of ileostomy and simplifies the procedure of colectomy at a later date. This method may be valuable, since chemotherapy (with sulfanilguanidine²⁸) can be applied directly to the diseased bowel. This at least offers possibilities for further study, both in regard to relief of symptoms and in regard to the preparation of the colon for removal.

Stone³² reports a method of performing a collecting reservoir of terminal ileum just proximal to the ileostomy for the purpose of decreasing the constant discharge of liquid contents. He used this procedure in 3 cases and was pleased with the results, since much of the fluid content was

absorbed from the pouch, thus producing a thicker and more easily managed ileostomy discharge.

McKittrick³³ has found that the preoperative use of the Miller-Abbott tube greatly facilitates colectomy in these cases. The small intestine becomes fluted on the tube, and so perfectly collapsed that it is easily kept out of the way during the removal of the colon.

IRRADIATION BURNS OF THE INTESTINE

White³⁴ reports 7 cases in which serious secondary involvement of the colon and ileum followed heavy radiation in the treatment of carcinoma of the cervix. 'This reaction has often been noted in mild degree, but in some cases such severe contraction of the intestine takes place that obstruction occurs. Fibrosis and ulceration are associated with bleeding and perforation. Temporary colostomy may be all that is needed in some cases of moderate severity, but permanent colostomy or resection is needed to relieve the more advanced lesions. White points out that the situation is probably far commoner than is recognized, and believes that often the symptoms are explained on the basis of a hopeless recurrence of the original disease, whereas as a matter of fact many such patients may be rescued by a proper surgical attack. Jones³⁵ and Todd³⁶ also call attention to rectal and intestinal complications following radiation for pelvic malignancy. Meigs³⁷ has had a similar experience.

CARCINOMA OF THE COLON AND RECTUM

Whipple³⁸ reports some striking results in surgery of the large bowel with the preoperative and postoperative use of the Miller-Abbott tube. In 76 cases of colon and rectal resections for carcinoma in various regions and by selective methods without the use of the Miller-Abbott tube there were 14 deaths, a mortality of 18 per cent. In 36 similar cases treated surgically in the same manner but with the use of the Miller-Abbott tube there was 1 death, a mortality of 3 per cent. Whipple thinks that the tube may replace any need for the two-stage operations in right colectomy but that, although it is valuable in the management of lesions of the left colon and rectum, it does not eliminate the need of colectomy.

Whipple points out the importance of having two members of the resident staff, a roentgenologist and a graduate nurse assigned to special duty for the introduction and management of the Miller-Abbott tube in large clinics. This is certainly advantageous in the formative period. As experience in this field accumulates, the difficulties and limitations of its use are becoming rapidly established. Ogilvie³⁹ has made an excellent report from Guy's Hospital on this subject. In my

opinion, it ranks second only to chemotherapy as the outstanding contribution to surgery during the past five years.

Coller, Kay and MacIntyre⁴⁰ have studied a group of specimens of rectal carcinoma clarified by the method used by Gilchrist and David.⁴¹ They found lymph-node involvement in 64 per cent of the cases studied, invasion of the blood vessels in 15 per cent. The age of the patient, the duration of symptoms, the size of the tumor and the size of the lymph nodes were unrelated to operability or to the lymph-node involvement and therefore to the prognosis. Anterior-wall lesions were more apt to reveal metastases. Only lesions within 3 cm. of the mucocutaneous junction showed lateral metastases. Above this region the spread of the disease was invariably upward or proximal to the lesion. Infiltrations through the wall of the bowel were accompanied by 91 per cent nodal involvement, whereas those confined to the wall showed 43 per cent metastatic nodes. Metastases were found in 81 per cent of sessile, 54 per cent of polypoid, and 33 per cent of excavating neoplasms. So far as could be determined, 28 per cent of all rectal carcinomas developed in polyps, and in another 42 per cent of the specimens benign polyps were also present.

LIVER

Ravdin⁴² presents experimental and clinical evidence that the liver may be protected from the damage inflicted on it by anesthesia and the other effects of any surgical procedure. He points out that carbohydrate is in itself insufficient, since its action is transient and the capacity of the liver cells for this substance is limited. Protein, on the other hand, is stored to better advantage and is utilized for liver-cell protection in a satisfactory manner. He suggests that the preoperative diet should contain approximately 70 per cent carbohydrate, 25 per cent protein and 5 per cent fat to obtain the maximum protection against liver damage.

Corriden⁴³ reports a successful operative procedure for extensive intracapsular hemorrhage of the liver. Confronted with a large bleeding cavity, he quickly detached the rectus muscle and filled the crater with it, holding it in place by loose sutures. The convalescence was stormy, but recovery took place.

Wallace⁴⁴ reports the successful removal of a large hepatoma involving a portion of the right lobe of the liver. The patient was symptom free after five years. He reviews the literature on the subject and brings it up to date.

PANCREAS

Morton and Widger⁴⁵ present an excellent paper

on the diagnosis and treatment of acute pancreatitis. They believe that there are three grades of this disease: the acute edematous, the hemorrhagic and the suppurative. Serum amylase determinations were more helpful than any symptoms, signs or other laboratory tests in establishing the diagnosis. Conservative treatment is advocated in all cases; in those which do not improve, operation may be beneficial. The operation should consist in biliary-tract drainage, the drainage of the abscess or necrotic area if it exists, but never incision of the pancreas itself. Unless an accurate diagnosis can be made, exploration is necessary to rule out a surgical emergency, such as perforation of peptic ulcer. In addition to the above, with which I agree, I should like to point out that persistent nausea in these cases may prevent adequate nourishment over too long a period. I have resorted to jejunostomy for feeding in these cases, with considerable satisfaction. Morton and Widger suggest that the pancreas is so like the parotid gland in structure that inflammation may respond to x-ray treatment in the former as it does in the latter. They have tried this form of therapy, giving only 250 to 450 r in broken doses of 50 to 100 r. Their early impression of this type of treatment is favorable.

David⁴⁶ reviews the literature and reports a case of his own of partial pancreatectomy for hypoglycemia. He concludes that in a patient with the Whipple⁴⁷ triad of symptoms (attacks of nervous or gastrointestinal disturbances coming on in a fasting state, associated with a hypoglycemia with readings below 50 mg. per 100 cc. and relieved immediately by ingestion of glucose), removal of the tail and body of the pancreas to the level of the superior mesenteric vessels is justifiable if careful search has failed to reveal an islet tumor. There was 1 death in 17 reported cases, and the results were satisfactory in 11. He questions the diagnosis in 2 of the remaining 4. The explanation of these good results is not clear, since hyperplasia of the islet cells was found in only 2 of the specimens. Normal pancreatic tissue was reported in 14 cases.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, MD, *Editor*

CASE 2/41

PRESENTATION OF CASE

A sixty five year-old artist entered the hospital complaining of abdominal pain.

Because of the patient's condition the history was obtained from his wife and his physician. Three years before admission the patient had an attack of upper abdominal pain situated near the midline. This pain was constant, nonradiating, lasted four days and was unaccompanied by fever, chills, vomiting, jaundice or back or shoulder pain. The patient remained well until three days before admission, when he was seized at 3 p.m. with a moderately severe pain in the right upper quadrant of the abdomen, accompanied by vomiting and anorexia. His physician found tenderness with slight spasm in the right upper quadrant just beneath the costal margin. The pulse was regular, the blood pressure 150 systolic, 90 diastolic, the pain was considerably alleviated by morphine. The patient had a fairly comfortable night with the aid of sedatives. In the morning the pain was less severe, but there was marked nausea in addition to the vomiting, and he complained of a burning or sour sensation in the stomach. The temperature was 99.5°F, the pulse was still regular. One day before admission there was slight residual pain, but his physician noted that the heart rhythm was completely irregular. The patient was unable to sleep that night because of pain and discomfort, and early in the morning recalled his doctor. The patient had vomited once during the night, the vomitus was watery and contained no blood. Examination revealed absence of abdominal tenderness, but a marked pulse deficit, in addition to auricular fibrillation. The patient had had a bowel movement the morning of the day the attack of pain began, but none thereafter, although he was given an enema on the day before admission. Following the onset of the attack, he had had no appetite and had eaten practically nothing.

One brother had died of tuberculosis, and the family, as a whole, was said to be subject to "mild rheumatism." The patient had had no serious previous illnesses.

On examination the patient was pale, extremely obese, drowsy, but in no apparent distress. The pupils were small, but equal, and reacted only slightly to light. There was no jaundice. The heart was not enlarged to percussion, but was fibrillating rapidly, with a marked pulse deficit. No evidence of valvular disease, gallop rhythm or accentuation of the pulmonic second sound was detected. Examination of the lungs was negative. The abdomen was somewhat tense throughout, with no areas of definite tenderness, peristalsis was present. There was no peripheral edema.

The temperature was normal, the pulse 135, and the respirations 22.

Examination of the urine showed a ++ test for albumin. Examination of the blood showed a red-cell count of 4,600,000 with a hemoglobin of 16.1 gm (photoelectric cell technic), and a white cell count of 36,500 with 91 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 28 mg per 100 cc; a blood Hinton test was negative.

X-ray films of the abdomen showed multiple stones, each about 1 cm in diameter, within the gall bladder. An electrocardiographic recording showed auricular fibrillation, with a rate of 140 to 150, the T waves were upright and of good amplitude, there was no abnormal axis deviation.

The patient was digitalized rapidly, and by the following day the ventricular rate had fallen to 115. Two days later the paroxysm of fibrillation had subsided, with the restoration of a regular rhythm at 88 per minute. The white cell count during this time swung between 14,000 and 22,000.

On the seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR HORATIO ROGERS: Are the x-rays pertinent?

DR AUBREY O. HAMPTON: These are apparently plain films of the gall bladder area. As the record stated the patient was very obese, and the films are therefore not so good as usual. The stones are obvious. The right side of the diaphragm is normal.

DR ROGERS: You cannot say anything about abnormal amounts of air in the intestines?

DR HAMPTON: The whole abdomen is not shown. One can see the region of the terminal ileum and ascending colon, which seems to be normal. There is a little gas in the terminal ileum, without dilatation.

DR ROGERS: The patient was sixty five and extremely obese, and in his past history he had had

one three-day episode of abdominal pain, which was not characteristic of gall-bladder disease or of duodenal ulcer, although it is said to have been in the upper abdomen. He was then well for three years and had an acute episode, which is very sparsely described. It started abruptly,—we may infer by the exactness of the hour,—with moderately severe pain accompanied by vomiting and anorexia, and the physician at that time noted nothing unusual about the pulse.

We then come to the admission to the hospital three days after the onset, when the patient was so sick that the history had to be taken from his wife and physician. He was drowsy but in no apparent distress. His pupils were small, but equal, and reacted only slightly to light. I suspect that morphine may have been part of the cause of his drowsiness. Later on, a nonprotein nitrogen determination showed that he was not in uremia. He presumably was not in diabetic coma, since there was no sugar in the urine; he must consequently have been very sick from his abdominal condition. But in spite of that the temperature was normal, although the white-cell count was 36,500 with 91 per cent polymorphonuclears. The abdomen was somewhat tense, but there were no areas of tenderness, and peristalsis was present. The patient did not have general peritonitis. His bowels had not moved, but he had eaten practically nothing since the onset. He had irregular fibrillation, and with digitalization, that subsided and a normal pulse returned. We are thus deprived of knowing what his pulse variations were during his preoperative hospital stay. An operation was then performed, apparently when he was somewhat better than he had been on admission.

There are a number of very interesting things about this case. To start with the most generalized considerations, the patient was relatively old, and he may have had cancer. If so, where would it be? Everything points to the right upper quadrant, and the only things that I can think of are the duodenum, the liver, the gall bladder, the bile ducts and the right colon. There is certainly nothing in the past history to suggest cancer. The episode three years previously does not fit in with cancer, in view of his subsequent good health. The abruptness of this recent episode, which brought the patient to the hospital, does not fit well with cancer unless we assume that a gradual occlusion had suddenly become complete. On the whole I do not believe that there is enough evidence to consider cancer very seriously.

The intestine might have been the cause of the trouble. The patient might have had a Richter's

hernia, either external or internal; but he was much too sick, and of course the story is not suggestive and there is not enough to consider that seriously. He might have had an appendiceal abscess, with a very high cecum. In people of sixty-five, particularly very obese people, the story and physical examination can be most obscure. He might have perforated his appendix at 3 p.m. without any prodromal symptoms that he could describe. Empyema of the gall bladder is also a possibility. We know that he had stones in his gall bladder, that he had some episode of upper abdominal pain three years before entry, and that this episode came on abruptly, as lodgment of a stone in the cystic duct might. The high white-cell count could be interpreted as evidence of undrained pus. The surgeons might not have felt the distended gall bladder because the patient was extremely obese. He had no jaundice, but he would not have had it if only the cystic duct had been obstructed, and that is all we can say for that.

The most striking disparity in this record is that between the white-cell count of 36,000 and the normal temperature. The likeliest explanation is a vascular accident. I can think of other things that could account for the high white-cell count and normal temperature—perhaps chemical peritonitis, perhaps certain neoplasms, perhaps a very sick or moribund patient who already had a leukocytosis but whose temperature had begun to go down with approaching death. On the whole some vascular accident seems likeliest in this man, who had a grossly abnormal vascular system. It is interesting that his abdominal symptoms began while his pulse was still regular. If he had had auricular fibrillation first, and then developed pain with this sequence of events, mesenteric thrombosis would be likelier, but that may be a minor point. Nothing is said about blood in the stools, because the patient did not have stools; he had no persistent tenderness, which I should expect if he had had mesenteric thrombosis. He did not have peritonitis enough to interfere with peristalsis. We have no x-ray evidence bearing on that. The distribution of the pain does not tell very much. It is simply under the costal margin. Nothing is said about radiation to the back. Nothing is said about the serum amylase; I assume it was not elevated, as it would be in pancreatitis.

It may not be quite fair, but one might ask what sort of operation was contemplated in a man in this condition, surely not any very radical or extensive surgery. Operation was performed with the idea of doing some small thing that was necessary, such as draining an empyema of the gall

bladder or relieving obstruction, rather than a resection for mesenteric thrombosis. If the patient did not need resection, the mesenteric thrombosis was best left alone.

Without more data I am merely guessing, but I hope I have at least mentioned what the condition really was. Either mesenteric thrombosis or empyema of the gall bladder seems probable, and I shall guess the latter.

DR. GRANTLEY W. TAYLOR: I think it would be interesting to have something on record indicating why operation was performed. We have his essentially negative physical examination, and in the laboratory work-up all we have is an elevated white cell count.

DR. TRACY B. MALLORY: Can you give any additional information, Dr. Welch?

DR. CLAUDE E. WELCH: I am the person alluded to as "the physician" in this case. I saw the man from the beginning through to the end, and although Dr. Rogers does not have all the details as we had them, we followed exactly his train of thought. In the first place here was a heavy man, weighing 250 pounds before he was taken ill. Two other things about his course at home and in the hospital seemed of importance. One, which Dr. Rogers has pointed out, was the extreme disparity between the white-cell count and the normal temperature, which persisted throughout. The second was the remarkable amount of pain, which the patient could not localize but nevertheless complained about bitterly, requiring large amounts of morphine. Physical examination throughout the stay in the hospital, as may be inferred from the notes, remained just about normal, with the exception of the finding, when he first came in, of definite tenderness and spasm in the right upper quadrant. During the first few days we considered that he probably had an acute gall bladder disease and that if we operated on him he would probably die; the latter turned out to be correct. We therefore treated him conservatively, despite the high white cell count, for nine days. As a matter of fact he was out of bed two days, and was apparently getting better. During that time an icteric index was taken, which was normal; Dr. Cope's laboratory reported a normal serum amylase. On the morning of the seventh day the patient suddenly had another severe attack of pain in the right upper quadrant and complained of increased pain, and again had spasm. Accordingly we believed that we were dealing with what had been acute gall bladder disease, which instead of subsiding had perforated. We decided that an emergency operation was indicated.

I think a little more discussion at this point might be pertinent.

DR. ROGERS: I should like to hear what his bowels did during the seven days.

DR. WELCH: He had had two or three small movements that were not abnormal. We were getting him out of bed, assuming he was well enough to go home, when the second episode happened.

DR. LELAND S. MCKITTRICK: Did he like food, or was it hard for him to eat?

DR. WELCH: He ate very little, and had no appetite.

DR. MCKITTRICK: I do not know what was the matter with him, but here and there in the story a number of things suggest pancreatitis, and I wonder how seriously it was considered. There are a number of things that are not quite right, it is true, but he had nausea and vomiting out of proportion to other things when the attack of pain came on. He had severe pain, but even when the pain was better he was uncomfortable and had nausea and vomiting. In other words, as I gather, he was quite uncomfortable in the hospital, at times without anything very definite to account for it. Dr. D. F. Jones used to lay a great deal of emphasis on indefinite, mild pain, persistent nausea and inability to eat, usually associated with deep tenderness along the course of the pancreas.

A PHYSICIAN: In the absence of pain in the back, how seriously would you consider pancreatitis?

DR. MCKITTRICK: Pain in the back may be important, but it is too often absent. To me it is of little or no help, and the diagnosis is frequently made without this symptom. The high white cell count without fever also suggests to me the possibility of pancreatitis.

DR. WELCH: We considered pancreatitis, but not seriously.

On opening the abdomen in the right upper quadrant no free fluid was found. The gall bladder was soft, contained stones, but was not acutely inflamed. When we lifted the transverse colon the pancreas could be felt; it was hard and enlarged one and a half times its normal size, with small areas of fat necrosis at the base of the transverse mesocolon. Accordingly, the gall bladder was emptied of stones, a drain put in, and the abdomen closed.

DR. MALLORY: Dr. Welch tells me that after operation the patient went along in much the same state for a few days, then had another extremely severe attack of pain and died very suddenly.

CLINICAL DIAGNOSES

Acute cholecystitis
Rupture of the gall bladder?

DR. ROGERS'S DIAGNOSIS

Empyema of the gall bladder?
Mesenteric thrombosis?

ANATOMICAL DIAGNOSES

Acute pancreatitis.
Chemical peritonitis.
Cholelithiasis.
Chronic cholecystitis.
Biliary cirrhosis of the liver, slight.
Rheumatic heart disease, with slight aortic and mitral stenosis.
Hypertrophy.
Obesity.

PATHOLOGICAL DISCUSSION

DR. MALLORY: At autopsy the chief finding was in the pancreas. At the time of operation it had been enlarged and hard; at the time of autopsy it was deliquescent. There was a mass of fluid, necrotic exudate, walled by chalky fat necrosis and a few recognizable remnants of pancreas. There was a slight diffuse chemical peritonitis. The heart was considerably hypertrophied, and showed mild chronic, rheumatic, mitral and aortic involvement. Microscopically the liver showed a trace of biliary cirrhosis.

DR. ROGERS: I am very glad Dr. McKittrick was here because otherwise the diagnosis would barely have been mentioned, certainly not discussed.

A PHYSICIAN: Should the serum amylase have given some help?

DR. WELCH: In this patient it was determined at a late stage of the disease, when it is often found to be normal.

CASE 27042

PRESENTATION OF CASE

A forty-nine-year-old Canadian housewife entered the hospital complaining of abdominal pain.

The patient had been perfectly well until eight months prior to entry, when, while doing some housework, she suddenly fainted and remained unconscious for about twenty minutes. After regaining consciousness she had a shaking chill for twenty minutes, followed by a sensation of warmth and diaphoresis. There were no other associated symptoms, and she remained well until two months later, when she had another severe chill, lasting for several hours, after which she had a drenching sweat. At this time she developed pain in the region of the umbilicus. The pain was rather sharp in character and rapidly increased in severity until it doubled her up; it gradually subsided in three or four minutes. These attacks recurred at irregular intervals, with varying severity, for about a week. During this period

the patient fainted five times. While suffering from pain she noticed a lumpy protrusion of her abdomen, which moved up and down and disappeared when the pain ceased. Her appetite was unimpaired, and there was no relation of the attacks to the ingestion of food. About four days after the onset of this episode, she had a sore throat for several days. She remained well thereafter until seven weeks before admission, and then began to have attacks of pain similar to those previously experienced. They still occurred in three-minute or four-minute cycles, but radiated from the umbilicus to the pubis and directly backward to the spine. The severity was generally increased, and the patient noted that "heavy" foods, particularly vegetables, appeared to aggravate the condition. There was never any nausea, emesis or melena, and her habitual constipation remained unchanged. She lost about 5 pounds during the eight months.

She had had mumps at twenty-two years of age, kidney trouble with the passage of "brick-dust" colored urine for five weeks at thirty-three, and diphtheria at thirty-five.

Physical examination showed a well-developed and well-nourished woman in no obvious distress. The heart was not enlarged. There was a soft systolic murmur at the apex. The blood pressure was 140 systolic, 80 diastolic. The lungs were clear. A visible swelling to the left of and below the umbilicus was caused by a firm, even, tender mass about the size of a baseball. There was an indefinite mass in the left upper quadrant, descending with respiration from beneath the costal margin. The liver edge was at the costal margin and appeared to be acutely tender. Considerable costovertebral tenderness was also elicited on the left. Vaginal examination showed a somewhat redundant anterior cervical lip. The cervix showed evidence of an old laceration, and there were many Nabothian cysts. The fundus was not definitely palpable, but the cervix moved on pressure beneath the abdominal mass. Rectal examination was negative.

The temperature, pulse and respirations were normal.

Examination of the urine was negative. The blood showed a red-cell count of 3,700,000 with a hemoglobin of 75 per cent, and a white-cell count of 7800 with 75 per cent polymorphonuclears. The stools gave a positive reaction to the guaiac test. The serum protein was 6.2 gm. per 100 cc.

A pyelogram showed both kidneys to be normal. A barium enema passed to the midpoint of the transverse colon, where complete obstruction was met. The obstructing defect corresponded to the palpable mass, which was readily movable but always with the transverse colon. There were ten-

derness and spasm in the right lower quadrant.

The patient remained comfortable after admission, although the temperature varied between 98 and 100°F., and the pulse between 80 and 90. Later examination showed the firm, round, tender mass previously noted, but none of the other abdominal findings were corroborated. On the fifth day an abdominal operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: We have in this case a forty-nine-year-old Canadian woman who was admitted to the hospital because of recurring attacks of unconsciousness, associated with severe chills on two occasions. The significance of these chills is rather difficult to determine, since we have no evidence that she had any fever with them, and the only temperature recordings we have are those of 98 and 100°F., after entry. The first attack of unconsciousness apparently was not associated with pain. The patient had five other attacks, however, that were apparently accompanied by severe abdominal pain. The note to the effect that she observed a lumpy protrusion of the abdomen, which moved up and down and disappeared when the pain ceased, is, I believe, of great importance in the diagnosis. It is rather strange that she apparently was well for a period beginning six months and ending seven weeks before admission, an interval of approximately four months. There is no question, however, that her symptoms became more marked in the last seven weeks before her admission, and her pains became more frequent. Of significance is the fact that the pain radiated from the umbilicus to the pubis and backward to the spine. Later she also observed that "heavy" food increased the pain, a thing which she had not noticed previously. In view of the x-ray findings, it seems extraordinary that her bowel habits remained unchanged. It is to be noted, however, that she is described as having been habitually constipated.

Physical examination is of interest because a mass was noted to the left and below the umbilicus. It was firm, even and tender, and about the size of a baseball. There was also a question of an indefinite mass in the left upper quadrant, descending with respiration. Pelvic examination was essentially negative. The fact that pressure beneath the abdominal mass produced movement of the cervix suggests to me that the abdominal mass was not connected to the uterus.

The laboratory studies are of importance in that they show a positive guaiac test in the stools. The blood counts show a secondary anemia, without leukocytosis.

There are a number of possibilities that enter my mind as explanations of these various symptoms and signs. In the first place, are we dealing with hyperinsulinism, that is, an adenoma of the islets of Langerhans, which of course could explain the symptoms of unconsciousness and also the severe chills? In answer to this, I believe the size of the abdominal mass and the fact that it was freely movable probably rule out this possibility.

Another condition that should be considered is that of cholelithiasis, with perforation of the gall bladder into the duodenum or colon and with a resulting obstruction of the bowel due to an impaction of a gallstone. I cannot rule out the diagnosis of cholelithiasis in this case, but it seems unlikely that the abdominal mass is due to an impacted gallstone in the intestines. In the first place, a gallstone usually becomes caught in the terminal ileum, and the fact that this patient's pain extended from the umbilicus to the pubis suggests that if she had intestinal obstruction, it was probably of the large bowel. In addition, she had no vomiting, a finding which is unusual in small-bowel obstruction.

Another possibility that enters my mind is an ovarian cyst with a twisted pedicle. The pelvic examination practically rules this out, and in addition the normal white-cell count hardly substantiates the diagnosis.

I think the most likely possibility is that this patient was suffering from some form of large-bowel obstruction. This is substantiated by the fact that she did have cramplike pains in her abdomen, which were chiefly felt below the umbilicus; this is characteristic of large-bowel pain. In addition, when she had the pain she noticed wavelike movements across her abdomen, which I interpret as intestinal peristalsis. The fact that she did not vomit suggests that her obstruction was in the large bowel and that it was only partial, which is also borne out by the fact that she was still having bowel movements. The positive guaiac reaction in her stools further bears out this diagnosis. It also indicates that we are probably dealing with a carcinoma which was ulcerating the bowel wall.

The x-ray studies give us additional information. A pyelogram of both kidneys showed that they were normal. The barium enema is of great significance in that it showed a complete obstruction of the transverse colon, which corresponded to the palpable mass in the abdomen. There was no evidence of displacement of the colon in the left upper quadrant, which probably rules out the presence of the indefinite mass in that region noted

on physical examination. The note made that after admission to the hospital, only the firm rounded mass was palpable also indicates this to be true.

In conclusion, my diagnosis in this case is carcinoma of the transverse colon, with almost complete obstruction. This does not explain satisfactorily to me the cause of the fainting spells and chills, but I do not see how it is possible to overlook the fact that by barium enema she had obstruction of the colon, or the fact that the mass felt in the abdomen was in direct relation to the point of obstruction. It is possible, I suppose, that the pains she suffered were severe enough to cause her to faint. I see no other way to explain them.

CLINICAL DIAGNOSIS

Carcinoma of hepatic flexure.

DR. LINTON'S DIAGNOSIS

Carcinoma of transverse colon.

ANATOMIC DIAGNOSIS

Lipoma of hepatic flexure.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: Diagnostic opinion on the wards closely paralleled the line of reasoning that Dr. Linton has set forth. There was speculation about the curiously intermittent character of the obstructive symptoms, but the x-ray report seemed to clinch the diagnosis of carcinoma of

the colon and the positive guaiac in the stools was cited as confirmatory evidence. The patient was therefore quickly prepared for operation and transferred to the surgical service.

On laparotomy Dr. Joe V. Meigs found a freely movable tumor in the hepatic flexure. The peritoneum was clear, but at one point the tumor seemed to have broken through the wall and to have marked the serosa. No doubt was felt that the lesion was carcinomatous, and a radical resection of the cecum, ascending colon and half the transverse colon was done with an anastomosis of the ileum to the transverse colon.

When the intestine was opened in the laboratory a pedunculated mass of tumor 6 by 4 by 4 cm. was discovered attached by a broad pedicle to the anterior wall of the hepatic flexure. The distal third of the tumor was greenish-black and obviously gangrenous. Beyond a sharp line of demarkation the remainder of the tumor was yellow and white, obviously consisting of a mixture of fatty and fibrous tissue. Microscopic examination confirmed the gross impression of a benign lipoma.

In retrospect, it is clear that the intermittent character of the obstruction was almost certainly due to attacks of intussusception, which are so frequent with polypoid tumors of the bowel. A lipoma would not, of course, be expected to produce a positive guaiac reaction, which was explained here by the partial gangrene of the tumor. Had the guaiac reaction been negative, the possibility of a benign tumor might have been more seriously considered.

COMMUNITY FUND

This editorial is about money: how much or how little of it to give, and how to give it for a cause that is ours. This year the goal of the two hundred and twelve agencies covered by the Community Fund is \$4,883,000. The campaign started January 18 and will continue until February 5, during which time the Physicians' Group is expected to raise \$20,500. This figure seems small; yet it, like the larger one, represents an increase of 5 per cent over last year. Will physicians meet this challenge?

Perhaps we should examine the records of past campaigns to try to arrive at an answer. Last year for the first time the physicians did not quite meet their quota. The reason for this may not

be single, but it is a fact that the number of them with incomes sufficient to allow them to give several hundreds of dollars is steadily declining. This year the number is even smaller. From this it seems clear that one way to offset this loss is to "broaden the base" of the giving; that is, more people must give a little more. We can possibly improve our status by examining the scale adopted for the contributors in industry, a copy of which is in the hands of each committeeman. In brief, the person earning an average weekly wage of twenty dollars is expected to contribute five dollars to the Community Fund. Very often he does contribute this, as do a great number of doctors' secretaries. Few of us are financially able to put down in cash what we know is our fair share in supporting this vast program. But one should remember that the participating agencies receive their allotments in periodic payments. Why not, then, give accordingly throughout the year? A physician who hands the committeeman a five-dollar bill could as easily give that much each month. In fact, one is urged to budget one's gift in any way one sees fit. Furthermore, it may be allotted to any one of the two hundred and twelve agencies listed on the designation sheet.

This yearly campaign is planned, not for the collection of money, but for the gathering of pledges. Let us pledge in proportion as we value our citizenship in a healthful, wholesome and stable community.

THE PRESIDENT'S BIRTHDAY

INFANTILE paralysis was first recognized as a clinical entity just one hundred years ago, and in 1916 our section of the country was first visited by a major epidemic of the scourge. Over thirteen years ago the Georgia Warm Springs Foundation was established, largely through the instrumentality of Franklin D. Roosevelt, himself a victim of the disease, and on September 23, 1937, the National Foundation for Infantile Paralysis was sponsored by President Roosevelt. On January 3, 1938, the foundation was incorporated as a nonprofit membership corporation under the laws of New York State.

Although the foundation has been functioning for over three years, its first annual medical meeting was held in New York City on November 7 and 8, 1940, and the report of this meeting has recently been released by the foundation's president, Basil O'Connor.* The foundation now functions in two fields: first, through its local activities as carried on by over a thousand chapters covering more than thirteen hundred counties in the United States, carrying aid to afflicted persons, and secondly, through its national activities, consisting largely of grants-in-aid to various institutions, covering investigations in five divisions—virus research, nutritional research, after-effects research, epidemiologic study and education.

Some of the activities of the foundation are listed by Mr. O'Connor in his report. Chemotherapy, as well as biotherapy, is being studied; \$243,000 was granted to the field of virus research alone during the last three years. A grant of \$37,500 was made for a clinical nutrition study of infectious diseases in human beings. Through the After-Effects Committee, \$221,000 was granted to physiologists, chemists and orthopedic surgeons in laboratories and hospitals. Nearly \$100,000 was expended in emergency medical services, public education and epidemiological studies. Since its organization, \$1,554,000, or about 50 per cent of the funds raised, has been left with the chapters throughout the country for their local use.

The National Foundation for Infantile Paralysis is an amazing and thoroughly unique organization. Far from representing the financial generosity of a single man or a single family, or the studied investment of an industry, it really belongs to the common people who support it. It has been animated by the courage and zeal and enthusiasm of an individual, and to the country at large it must represent a triumph of unselfish devotion. It may well be ranked as a modern crusade.

The support of the foundation comes largely from the celebration of the President's birthday, which falls on January 30; a celebration that has been held annually since 1934, the proceeds of the

first four years going to the Georgia Warm Springs Foundation. The conquest of the virus diseases, of which infantile paralysis is one of the four horsemen, is a major medical problem facing us today. The National Foundation for Infantile Paralysis has proved its earnestness, its integrity, its worthiness. It deserves universal support.

PSYCHIATRY AND THE SELECTIVE SERVICE SYSTEM

World War I showed clearly the importance of excluding army recruits who showed signs of nervous or mental instability and hence were liable to be a burden instead of an asset and later to cause great expense to the country on account of hospitalization and compensation. Although methods for carrying out the preliminary examination of draftees in the last war left much to be desired, results of great value were obtained. The Selective Service System is at present faced with this same problem.

For the purpose of co-ordinating the work of the physicians who are dealing with the problem of mental and nervous stability the Selective Service System has arranged seminars where examining physicians of the local draft boards and psychiatrists of the medical-advisory and induction boards can meet together, discuss the problems, and come to some agreement about methods, standards and terminology.

The first regional seminar was held in Washington, D. C., on January 2 and 3. It was opened by Director Dykstra and was addressed in an evening session by the Honorable Paul V. McNutt. The second regional seminar, arranged for the New England area, is to be held in Boston on January 30 and 31, and the program appears in this issue of the *Journal*. It is hoped that all examining physicians, medical-advisory-board psychiatrists and induction-board psychiatrists from the New England states who are able to attend will do so. Members of the medical profession who are interested in nervous and mental disorders will be welcome at the seminars, and attendance at the evening meeting should prove profitable to those leaders in community activity who are particularly con-

cerned with mental hygiene, social organization and welfare, and problems of individual adjustment.

MEDICAL EPONYM

FRÖHLICH'S SYNDROME

On October 12, 1901, Dr. Alfred Fröhlich (b. 1871), an associate of Nothnagel in the First Medical Clinic in Vienna, gave a demonstration before the Society of Psychiatry and Neurology in Vienna. His discussion, including a case report and references to the literature, was published in the *Wiener Klinische Rundschau* (15: 883-886, 906-908, 1901), under the title "Ein Fall von Tumor der Hypophysis cerebri ohne Akromegalie [A Case of Tumor of the Hypophysis Cerebri without Acromegaly]." A portion of the translation follows:

I may repeat that in our case, along with the adiposity, other symptoms are present which make it seem apparent that these are to be regarded as trophic disturbances. Thus the scanty growth of hair, with loss of hair, the lack of hair in the axillae, the development of the breasts, the peculiar character of the pubis recalling the female genitals. . . . I have already spoken of the subjective sensation of chilliness and the dryness of the skin. Consequently there is present at least the suggestion of a myxedematous condition. . . . From these facts it may, therefore, be concluded that in the presence of symptoms suggesting a tumor in the region of the hypophysis and in the absence of acromegalic symptoms, the existence of trophic disturbances elsewhere, such as rapidly developing obesity or changes in the skin resembling myxedema, points to the hypophysis itself as the origin of the new growth.

PREGNANCY IN A PATIENT WITH MITRAL STENOSIS

Mrs. M. C. W., a twenty-four-year-old para III at term, was admitted to the hospital on June 25, 1935, not in labor, with a diagnosis of rheumatic

heart disease, mitral stenosis and insufficiency, aortic insufficiency and cardiac decompensation.

The patient had had rheumatic fever in 1931, in the fifth month of her second pregnancy, and was confined to bed for about ten weeks. The pregnancy went to term, and during the last month the patient had dyspnea, orthopnea, palpitation and edema. Following a normal delivery in May, 1931, the patient was in such a poor condition that she was kept in bed in a hospital for forty-three weeks. She then returned home on limited exercise and digitalis. Her first pregnancy terminated in a normal delivery in June, 1929. Catamenia began at twelve, were regular with a twenty-eight-day cycle and lasted four days without pain. The last normal period began on October 5, 1934, making the expected date of confinement, July 12.

On her first visit to the prenatal clinic the patient was advised to go to the hospital. During the month prior to her admission she had numerous attacks of palpitation with dyspnea and orthopnea, without edema. Three weeks before admission the patient had an attack of palpitation lasting six hours. The patient was kept in bed during this time. There was no hemoptysis, cough, hoarseness, fainting spells, vertigo, scotomas or epigastric pain.

Physical examination at the time of admission showed a well-developed and well-nourished woman. The heart showed presystolic and systolic murmurs at the apex transmitted to the axilla. There was a diastolic murmur to the left of the sternum. The blood pressure was 160 systolic, 120 diastolic. The lungs were clear. There was edema of the ankles. The fundus was enlarged to a size consistent with the period of amenorrhea. The vertex was presenting in the pelvic brim, in an LOA position, and the fetal heart was audible.

Three days after admission the membranes were ruptured artificially. Following this, the patient had a few slight back pains. At midnight she was having an occasional contraction, but the cervix showed no change. At 1:12 a.m. 1 minim of Thyrophysin was given, and the patient started in good labor. The fetal heart at this time was somewhat rapid and irregular. When only a rim of cervix remained, drop-ether anesthesia, with oxygen, was started. The patient did not look well at this time, although the pulse was 80 and of good quality; and she soon became cold and clammy. The fetal heart could not be heard. Induction of anesthesia was very slow, deliberate and careful. Forceps were applied, and the head was delivered without traction. The baby was in very poor condition and required a great deal of resuscitation. It finally began to breathe fairly well but in a jerky manner.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

The mother's condition was satisfactory immediately following delivery, and she made an uneventful convalescence. The baby, however, died the day after delivery, and autopsy showed hemorrhage around the adrenal gland. The diagnosis was believed to be hemorrhagic disease of the newborn. The mother was discharged on July 21, obstetrically well with medical complications.

Comment. This patient was very severely ill. The method of delivery may well be criticized. The dictum that a cardiac patient should not have labor induced at any time for any reason is sound, and there was no very good reason for giving it up in this case.

The patient, having had cardiac decompensation, is classified as a Class 1A cardiac. In the first place, she should not have become pregnant; in the second place, she should have had her pregnancy terminated early, had she been seen at that time.

When first seen in the clinic, she showed early signs of decompensation. A much longer period of hospitalization before delivery would have been advisable.

When the patient again became pregnant, a therapeutic abortion was performed.

normality in the blood picture should be regarded with suspicion. Tests for sulfate excretion in the urine should also be made, according to the method of Yant, Schrenk, Sayers or others.

Q. I am plant physician for a small concern in which I suspect several men are exposed to harmful quantities of lead fumes. Where can I have the air analyzed to see how much lead is present, and where can I have urine samples examined to determine the amount of lead?

A. Your compensation-insurance carrier will probably do this for you; if not, the matter should be referred to your state department of industrial hygiene, provided it is equipped to make such examinations.

Q. Assuming that all precautions have been taken to prevent lead absorption, what method of examination should be used periodically on exposed employees?

A. In cases of moderate exposure, a routine examination of blood smears for stippling, a general physical examination and an examination of the urine for lead should be conducted quarterly.

Q. What is a safe procedure to use in the re-employment of a person with arrested tuberculosis?

A. Assuming that the tuberculosis has been arrested, the following conditions should hold on re-employment: careful, frequent check by x-ray and sputum examination; no exposure to dust; no strenuous exertion, particularly that involving stretching motions; adequate ventilation; and adequate rest.

Q. When should shop workers exposed to dust wear respirators?

A. Respirators should be worn when either siliceous or non-siliceous dust is present in large amounts. They should be used, however, as adjuncts to exhaust methods of dust removal, rather than as substitutes. Respirators are particularly necessary when the dust contains free silica (SiO_2) in amounts exceeding 1 per cent, which cannot be controlled by engineering methods.

Q. Please send me a list of simple approved respirators which can be used by workers in a moderately dusty atmosphere. The dusts are not specifically harmful, being of a vegetable nature.

A. Specific dust problems should be discussed with your state department of industrial hygiene.

COMMITTEE ON INDUSTRIAL HEALTH

QUESTIONS AND ANSWERS

Q. In one of our departments we are contemplating the installation of a large number of fluorescent lights. Some rumors are going around among the employees that exposure to these lights has an effect on the ovaries and may even cause sterility. Could you provide me with any information on this subject?

A. There is no more reason to anticipate harmful effects from this light than from other illuminants, such as tungsten filament lamps and Cooper-Hewitt mercury arcs.

Q. I am consultant to a plant in which large quantities of benzol are used in the manufacture of certain industrial chemicals. This benzol is normally kept in an entirely enclosed system, but there is some unavoidable inhalation of benzol vapor by maintenance and repair workers. There are reports in the literature of fatal cases of benzol poisoning in workers with very low-grade exposure to benzol. What steps should I take to make sure that no such cases occur?

A. Frequent examination should be made of those exposed to any concentration of benzol. Any ab-

where full and complete information as to the various types of respirators may be obtained

MEDICAL POSTGRADUATE EXTENSION COURSES

The following sessions, given by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, have been arranged for the week beginning January 26

MIDDLESEX EAST

Tuesday, January 28, at 4 15 p.m., at the Melrose Hospital, Melrose Pediatric Case Discussions
Instructor R Cannon Eley Walter H Flanders,
Chairman

MIDDLESEX SOUTH

Tuesday, January 28, at 4 00 p.m. at the Cambridge Hospital, Mt. Auburn Street, Cambridge Diet and Vitamins in Surgery Instructor Charles C Lund Dudley Merrill, *Chairman*

NORFOLK

Thursday, January 30, at 8 30 p.m., at the Norwood Hospital, Norwood Technique and Treatment of Primary, Secondary and Tertiary Syphilis Instructor C Guy Lane Hugo B C Reiner,
Chairman

NORFOLK SOUTH

Monday, January 27, at 8 30 p.m., at the Quincy City Hospital, Quincy Recent Advances in Medical Therapeutics Instructor Charles A Janeway David L. Belding, *Chairman*

SUFFOLK

Thursday, January 30, at 4 30 p.m., in John Ware Hall, Boston Medical Library Chemotherapy in the Treatment of Gonococcal Infection Instructor Oscar F Cox Reginald Fitz, *Chairman*

DEATHS

DAVIS—CHARLES H DAVIS, M.D., of South Hamilton, died January 15 He was in his sixty ninth year

Born in Somerville, he attended Harvard University and received his degree from Harvard Medical School in 1899 He practiced in Beverly for four years, one of which he served as city physician He went to South Hamilton in 1905

Dr Davis was a fellow of the Massachusetts Medical Society and of the American Medical Association

His widow, a daughter and two sons survive him

DECKER—JOHN J DECKER, M.D., of Sioux City, Iowa, died December 18 He was in his thirty seventh year

He received his degree from the University of Wisconsin Medical School in 1931 and interned for one year at the Bell Memorial Hospital, Kansas City, Kansas From 1933 to 1938 he was assistant superintendent of the Lakeville State Sanatorium in Middleboro Dr Decker took a general surgery internship at the Carney Hospital from 1938 to 1939 For the fourteen months before his death, he was in general practice and surgery in Sioux City, Iowa

Dr Decker was a fellow of the Massachusetts Medical Society and of the American Medical Association

His widow and a daughter survive him

HENRY—JOHN G HENRY, M.D., of Winchendon, died January 18 He was in his eighty fourth year

He received his degree from Dartmouth Medical School in 1881 At the time of his death he was president of the Millers River Hospital, Winchendon Dr Henry was a fellow of the Massachusetts Medical Society and the American Medical Association He also held memberships in the New England Obstetrical and Gynecological Society and the American College of Surgeons

HUBBARD—OSWYN H HUBBARD, M.D., of Gilsun, New Hampshire, died January 5 He was in his eightieth year

Dr Hubbard received his degree from McGill University Faculty of Medicine in 1888 He was a member of the Massachusetts Medical Society and the American Medical Association

HUTCHINGS—J HENRY HUTCHINGS, M.D., of Woburn, died January 12 He was in his seventy ninth year

He attended Tufts College and received his degree from New York University Medical College in 1887 He interned at Charing Cross Hospital, London, and studied in Vienna before returning to begin practice here

Dr Hutchings was a fellow of the Massachusetts Medical Society and the American Medical Association

His widow survives him

KRAMER—FLORENCE KRAMER, M.D. of Lynn died at Miami Beach, Florida January 15 She was in her fifty-eighth year

Born in New York City, she received her degree from Loyola University School of Medicine in 1918 and first practiced surgery in the coalmining district of West Virginia

She was a member of the Massachusetts Medical Society and the American Medical Association and secretary of the North Shore Medical Society

Her widower, Dr Maurice Reingold survives her

MURPHY—EDWARD F MURPHY, M.D., of Jamaica Plain, died January 15 He was in his sixty fifth year

Born in St John, New Brunswick he received his degree from McGill University Faculty of Medicine in 1899 and was a member of the staff of the Royal Victoria Hospital, Montreal Since 1901 he had been in general practice in Boston, and during World War I was a captain in the medical corps

Dr Murphy was a fellow of the Massachusetts Medical Society and of the American Medical Association He was a former staff member of St Elizabeth's Hospital and at the time of his death was president of the Forest Hills Hospital He had been chief medical examiner for the law department of the City of Boston for the past ten years and was a member of the Massachusetts Society for Examining Physicians

His widow, a daughter, three brothers and two sisters survive him

WALTON—GEORGE L WALTON, M.D., of Boston died January 17 He was in his eighty-eighth year

Born in Lawrence, he attended Williston Seminary and Harvard University, and received his degree from the Harvard Medical School in 1880 The following three years were spent studying in Europe as a Parker Fellow in the Study of Neurology From 1900 to 1906 he was clinical instructor in the Department of Diseases of the Nervous System at Harvard Medical School Dr Walton had also served as physician and consulting physician to

the Neurological Department of the Massachusetts General Hospital.

He was a member of the Massachusetts Medical Society, the American Medical Association, the American Neurological Association and the Boston Society for Psychiatry and Neurology.

CORRESPONDENCE

MASSACHUSETTS STATE GUARD

A number of doctors are needed for duty as medical officers with the new Massachusetts State Guard which is now being formed. This volunteer organization will function in place of the Massachusetts National Guard, which is being inducted into federal service. It will be trained to cope with any emergency situation that might occur within the Commonwealth and which might overtax the capacities of civilian organizations.

A doctor, after receiving his commission, at the outset will have to devote a certain number of evenings to the examination of recruits, and thereafter will be expected to give one evening a week to drill, training and other routine duties. Full-time service will be required only in the event of some emergency, and will be limited to within the State.

The requirements of the physical examination are not strict. Previous military experience is desirable but not a necessary prerequisite. It is not expected that this duty will interfere materially with one's private practice. Any interested medical men will please communicate promptly with the undersigned, stating briefly their age, qualifications, and previous military experience, if any. Outside the Greater Boston area, there is need for one or more men in or near Brockton, Fall River, Framingham, Holyoke, Lawrence, Lynn, New Bedford, Pittsfield, Plymouth, Salem, Springfield and Worcester.

RICHARD H. MILLER, M.D., *Chief Surgeon*.

264 Beacon Street,
Boston.

DEPRIVATION OF LICENSE

To the Editor: At the meeting of the Board of Registration in Medicine held January 9, the Board canceled the registration as a practitioner of medicine in this commonwealth and revoked the certificate of registration of Dr. Daniel Nyman, 9 Jason Street, Arlington, Massachusetts, because of gross professional misconduct in connection with a case of abortion.

STEPHEN RUSHMORE, M.D., *Secretary*,
Board of Registration in Medicine.

State House,
Boston.

NOTICES

ANNOUNCEMENT

GERALD I. LICHTER, M.D., announces the removal of his office from the Boston City Hospital, Boston, to 1421 Main Street, Springfield.

BOSTON TUBERCULOSIS ASSOCIATION

The Boston Tuberculosis Association is holding its annual meeting at the Women's Republican Club, 46 Beacon Street, Boston, on Friday, January 31, at 4:30 p.m.

The meeting will be followed by a dinner at 6:15 p.m., attended by members and guests of the Southern Middlesex Health Association, Boston Tuberculosis Association,

Norfolk County Health Association, Newton Family Service Bureau, Cambridge Tuberculosis and Health Association, Essex County Health Association, Lawrence Tuberculosis League, Lowell Tuberculosis Association, Lynn Tuberculosis League, Malden Tuberculosis and Health Association, Salem Association for the Prevention of Tuberculosis, Southwestern Middlesex Public Health Association, Southern Worcester County Health Association, Massachusetts Tuberculosis League and the Trudeau Society of Boston. The after-dinner speaker will be Dr. Bruce H. Douglas, tuberculosis controller, Detroit Department of Health, whose subject is "Present-Day Problems in the Control of Tuberculosis."

MASSACHUSETTS GENERAL HOSPITAL

A meeting of the Hospital Research Council will be held in the White Auditorium of the Massachusetts General Hospital on Tuesday, January 28, at 5:00 p.m.

PROGRAM

Nutritional Factors in Obstructive Jaundice in Relation to Treatment. Dr. John D. Stewart and Miss G. Margaret Rourke.

Diagnostic Value of Synovial Fluid Analyses. Drs. Marian W. Ropes, Howard C. Coggeshall and Walter Bauer.

A Classification of the Various Types of Male Eunuchoidism from an Endocrine Point of View. Drs. Fuller Albright, Anne P. Forbes, R. Bretney Miller and Russell Frazer.

Dr. A. L. Watkins invites all who are interested visit the Department of Physical Therapy at 4:30 p. just before the meeting.

BOSTON DOCTORS' SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will rehearse under Alexander Thiede, formerly concert master of the Cleveland Symphony Orchestra, every Thursday at 8:30 p. Those interested in becoming members should communicate with Dr. Julius Loman, Pelham Hall Hotel, Brookline (BEA 2430).

BOSTON MEDICAL HISTORY CLUB

There will be a meeting of the Boston Medical History Club on Monday, January 27, at the Boston Medical Library, 8 Fenway, Boston, at 8:15 p.m. Dr. Harold F. Plough, Rufus Tyler Lincoln Professor of Biology, Amherst College, will speak on "Human Genetics in Relation to Medicine."

All interested persons are cordially invited to attend.

GREATER BOSTON MEDICAL SOCIETY

There will be a meeting of the Greater Boston Medical Society on Tuesday, February 4, in the auditorium of the Beth Israel Hospital at 8:15 p.m. Dr. David I. Macht, of Baltimore, Maryland, will speak on "Experimental and Therapeutic Researches on Snake Venoms." Discussion will follow by Drs. Hyman Morrison and Harry Blotner.

MASSACHUSETTS PSYCHIATRIC SOCIETY

There will be a meeting of the Massachusetts Psychiatric Society at the Boston Psychopathic Hospital on Friday, January 31, at 8 p.m.

PROGRAM

- The Evaluation of Intellectual Deterioration Dr David Shakow
 Procedures for the Study of Personality Through Educated Phantasies Dr S Rosenzweig
 Some Techniques for the Measurement of Psychophysiological Function. Dr E H Rodnick

TRUDEAU SOCIETY OF BOSTON

There will be a meeting of the Trudeau Society of Boston at the Beth Israel Hospital on Friday, January 31, at 8 p.m. Dr Bruce H Douglas, of Detroit, Michigan, will speak, his subject being "Methods in Tuberculosis Case Finding."

Physicians and students are cordially invited

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held on Tuesday, January 28, in the amphitheater of the Peter Bent Brigham Hospital at 8 15 p.m. Dr Elliott C Cutler will preside.

PROGRAM

- Presentation of cases
 Carcinoma of the Pancreas Dr Frank Glenn, assistant professor of surgery, Cornell University Medical College.

JEWISH MEMORIAL HOSPITAL

There will be a staff meeting of the Jewish Memorial Hospital on Wednesday, January 29, in the hospital auditorium, 45 Townsend Street, Roxbury, at 8 30 p.m.

PROGRAM

- Recent Advances in the Treatment of Mental Diseases
 Dr Abraham Myerson
 Collation

All interested physicians are cordially invited to attend

CONSULTATION CLINIC FOR CRIPPLED CHILDREN IN MASSACHUSETTS, UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Salem	February 3	Harold C Bean
Haverhill	February 5	William T Green
Lowell	February 7	Albert H Brewster
Gardner	February 11	Mark H Rogers
Brockton	February 13	George W Van Gorder
Pittsfield	February 17	Frank A Slowick
Northampton	February 19	Garry deN Hough, Jr
Fall River	February 24	Eugene A McCarthy
Hyannis	February 25	Paul L Norton
Worcester	February 28	John W O'Meara

NORFOLK DISTRICT MEDICAL SOCIETY

A regular meeting of the Norfolk District Medical Society will be held at the Carney Hospital, South Boston, on Tuesday, January 28, at 8 30 p.m.

PROGRAM

- Business
 Papers and case presentations by the hospital staff
 Discussion
 Collation

NEW ENGLAND PEDIATRIC SOCIETY

There will be a meeting of the New England Pediatric Society on Wednesday, January 29. The clinical presentation will be held in the amphitheater, Joseph H Pratt Diagnostic Hospital, and all other events at Longwood Towers, Brookline.

PROGRAM

- 4 00 Clinical meeting, Boston Floating Hospital Dr Elmer W Barron and his associates
 6 30 Refreshments
 7 00 Dinner
 8 00 Annual meeting of the society
 Election of officers
 Report of treasurer
 8 30 Pathologic Aspects of Adiposity Dr Sidney Farber

SELECTIVE SERVICE SYSTEM SEMINAR ON PSYCHIATRIC PROBLEMS

A seminar on psychiatric problems, arranged for the benefit of the examining physicians of the local draft boards and the psychiatrists of the medical advisory and induction boards, will be held in Boston on January 30 and 31. Dr Karl M Bowman, of New York City, will be the presiding chairman. The program is as follows:

JANUARY 30

Morning Session 10 30 a.m. Boston Medical Library

- Introduction Brigadier General Edgar C Erickson
 Remarks on the Medical Work of the Selective Service System Donald E Currier, M.D.
 Psychiatric Factors in the Medical Examination Joseph H Pratt M.D. professor of clinical medicine, Tufts College Medical School
 Military Psychiatry and the Selective Service System Lieutenant Colonel W C Porter
 Psychiatric Experience of the Veterans Administration Martin Cooley, M.D.

Afternoon Session 2 00 p.m. Boston Medical Library

- Practical Psychiatry Harry S Sullivan M.D.
 Informal discussion
 Synthesis of the discussion Dr Sullivan

Evening Session 8 30 p.m. Hotel Statler

- Dr W G Shippen, president, Massachusetts Medical Society, chairman
 National Defense and Selective Service Robert T Bushnell, attorney general of Massachusetts
 What the Medical Profession Expects from Psychiatry Lieutenant Colonel Elliott C Cutler, M.R.C.
 Selective Service and Psychiatric Issues C Macfie Campbell, M.D., medical director, Boston Psychopathic Hospital

JANUARY 31

(Each presentation will be followed by informal discussion by the panel of psychiatrists from the medical advisory boards and the induction boards.)

Morning Session, 9:30 a.m., Boston Medical Library

Peculiar Personalities: Mood disorders and psychopathic personalities. Karl M. Bowman, M.D., director of psychiatry, Bellevue Hospital, New York City.

Disorders with Structural Features: Mental defect and deficiency, posttraumatic encephalopathy, post-encephalitic changes, epilepsy and related states, and conditions associated with somatic disease and injury. Harry C. Solomon, M.D., associate professor of psychiatry, Harvard Medical School.

Psychosomatic Disorders. Abraham Myerson, M.D., clinical professor of psychiatry, Harvard Medical School.

Afternoon Session, 2:00 p.m., Boston Medical Library

The Psychoneuroses and Malingerings. Francis H. Sleeper, M.D., director of hospital inspection, Massachusetts Department of Mental Health.

Schizophrenic and Related Personalities. Douglas A. Thom, M.D., professor of psychiatry, Tufts College Medical School.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, JANUARY 26

SUNDAY, JANUARY 26

14 p.m. Medical Aids to Justice. Dr. Alan R. Moritz. Free public lecture. Harvard Medical School, Building D.

14 p.m. Orthopedics and the Layman. Dr. Robert H. Morris. Public health lecture. Cambridge Hospital, Margaret Jewett Hall.

MONDAY, JANUARY 27

12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

*8:15 p.m. New England Heart Association. Peter Bent Brigham Hospital.

*8:15 p.m. Human Genetics in Relation to Medicine. Dr. Harold H. Plough. Boston Medical History Club. Boston Medical Library, 8 Fenway.

TUESDAY, JANUARY 28

*9-10 a.m. Clinic on Tumors of the Breast. Dr. W. M. Shedden. Joseph H. Pratt Diagnostic Hospital.

12:15-1:15 p.m. Clinicorontgenological conference. Peter Bent Brigham Hospital amphitheater.

5 p.m. Hospital Research Council. Massachusetts General Hospital, White auditorium.

8:15 p.m. Harvard Medical Society. Peter Bent Brigham Hospital amphitheater.

WEDNESDAY, JANUARY 29

*9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.

*12 m. Clinicopathological conference. Children's Hospital.

*2-4 p.m. Endocrine Disorders. Drs. R. Loeb and E. C. Cutler. Peter Bent Brigham Hospital.

4-8:30 p.m. New England Pediatric Society. Joseph H. Pratt Diagnostic Hospital and Longwood Towers, Brookline.

*8:30 p.m. Jewish Memorial Hospital, 45 Townsend Street, Roxbury.

THURSDAY, JANUARY 30

*8:30 a.m. Combined clinic of the medical, surgical, orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital, at the Peter Bent Brigham Hospital.

*9-10 a.m. Sulfathiazole in Gonococcal Infections. Dr. O. F. Cox. Joseph H. Pratt Diagnostic Hospital.

Selective Service System Seminar. Boston Medical Library, 8 Fenway.

*5 p.m. Vitamin K: Its general significance in biochemistry, and its role in human pathology and its application in therapeutics. Dr. Henrik Dam. Cutter Lecture on Preventive Medicine. Harvard Medical School, amphitheater of Building E.

FRIDAY, JANUARY 31

*9-10 a.m. Clinicopathological conference. Drs. J. C. Aub and H. E. MacMahon. Joseph H. Pratt Diagnostic Hospital.

Selective Service System Seminar. Boston Medical Library, 8 Fenway.

4:30 p.m. Boston Tuberculosis Association. Women's Republican Club, 46 Beacon Street, Boston.

*8 p.m. Methods in Tuberculosis Case Finding. Dr. Bruce H. Douglas. Trudeau Society of Boston. Beth Israel Hospital.

8 p.m. Massachusetts Psychiatric Society. Boston Psychopathic Hospital.

*Open to the medical profession.

†Open to the public.

BOOK REVIEW

A Method of Anatomy, Descriptive and Deductive. By J. C. Boileau Grant, M.C., M.B., Ch.B., F.R.C.S. (Edin.). Second edition. 4°, cloth, 794 pp., with 651 illustrations. Baltimore: Williams & Wilkins Company, 1940. \$6.00.

This second edition, much improved by new textual discussions and by one hundred additional illustrations, should make a strong appeal to students. The author presents his subject in a stimulating manner, well calculated to stir the imagination and the interest of his readers. Mutual relations of facts and their correlation with clinical data constitute an important aspect of the book. Those who are familiar with the first edition will want to own a copy of the new one.

EXPLORATION AND DIVISION OF THE FEMORAL AND ILIAC VEINS IN THE TREATMENT OF THROMBOPHLEBITIS OF THE LEG*

JOHN HOMANS, M.D.†

BOSTON

EXPLORATION of the femoral and iliac veins has been found useful in treating some of the varieties of thrombophlebitis peculiar to the leg. As in other comparatively untried procedures, its indications are not as yet clear. The radical surgeon will use it too often; the conservative, too seldom. Its principal indication is undoubtedly to prevent pulmonary embolism, but it may be called for to correct peripheral vasospasm in the limb served by the diseased vein, to oppose recurrence of attacks of femoroiliac thrombophlebitis and, conceivably, once the femoral vein has suffered destruction of its valves by earlier attacks, to prevent backflow down the vein, the same purpose for which a varicose vein is divided at the groin. No other indications, however, can compare in importance with preventing the detachment of an embolus. And the most frequent source of embolism, in my opinion, is the so-called "bland" type of thrombosis, especially the sort that originates in the deep veins below the knee.

THROMBOPHLEBITIS IN THE DEEP VEINS OF THE LOWER LEG

Occurring During Active Life

In 1934, I¹ read a paper before this society on "Thrombosis of the Deep Veins of the Lower Leg, Causing Pulmonary Embolism," based on four cases, in one of which (A.F., 1929) I successfully divided the superficial femoral vein at the groin. This operation was performed at the request of Dr. Channing Frothingham, who had seen another of his patients die, without operation, under exactly similar conditions of disease. Since that time, I have treated five other patients, not one of whom has suffered a pulmonary embolism, and two of whom I have operated on with

success. For the sake of clarity, let it be understood that I am alluding, for the moment, only to thrombophlebitis in the deep veins of the calf, occurring during active life; that pulmonary embolism has been held in each case to be threatened; that treatment has been directed principally against that accident; that the patients were young or middle-aged, and free from antecedent disease; and that the diagnosis rests on the following findings: the patient experiences lameness on walking, especially when going up or down stairs; such swelling and cyanosis as are present are confined to the lower leg, that is, entirely below the thigh; there is no generalized edema as in phlegmasia alba dolens; the *dorsiflexion sign*—discomfort behind the knee on forced dorsiflexion of the foot—is *positive*; swelling and cyanosis are always relieved by a few days' rest in bed (in contrast to femoroiliac thrombophlebitis), and in several cases, ineffectually treated, have recurred more than once.

The treatment consists of rest in bed, the foot of which is elevated from 10 to 15 cm. The leg is sometimes placed on a small, soft pillow for comfort, but is otherwise left free. The active venous return so secured is believed to limit the progress of thrombosis and to lead to healing. The swelling and cyanosis, if any, always disappear in a few days, but the dorsiflexion sign usually lasts for a week or more. At the end of ten days, all signs of disease having gone, the leg is actively used in bed, the foot being exercised first, then the knee and thigh, as in riding a bicycle. After four days of this treatment the leg is bandaged from toes to knee with semielastic cotton bandage, and the patient begins to walk. If none of the original signs recur, he is allowed, about three weeks from the time he went to bed, to resume a full, active existence.

If, on the other hand, when the patient first gets up, the discomfort, edema and especially the

†Clinical professor of surgery, Tufts College Medical School; chief of Circulatory Clinic, Boston Dispensary.

dorsiflexion sign reappear, the superficial femoral vein is at once exposed and divided. Operation is recommended also when the patient, before being seen, has already undergone several episodes of bed rest and relapse.

A case in point, fairly representative of the three that I have treated by operation, is the following:

S. G., a healthy 18-year-old college girl, had recently driven an automobile across the continent. On arriving, she felt her right leg to be lame, and after a day or two I found her ankle to be slightly swollen, the foot faintly cyanotic. The dorsiflexion sign was strongly positive. After 2 weeks of treatment by elevation of the leg in bed, she seemed to have fully recovered and was allowed gradually to get about in a semielastic cotton bandage. Almost at once, however, the lameness and swelling reappeared and discomfort on dorsiflexion recurred. Accordingly, the superficial femoral vein at the groin was explored, was found to contain no clot at this level and was divided. After a week in bed and a second week of convalescence, the girl was able to ignore the leg, which never again exhibited lameness or swelling.

Thus the division, primarily intended to forestall embolism, rapidly and permanently relieved the patient of all signs of the disease. Such an optimistic statement is justified by exactly similar results in two other cases, one, a woman of thirty-five, the other, an athletic man of forty-five. It will be understood, of course, that three other patients recovered completely, without operation, under the scheme of treatment outlined.

All this I¹⁻³ have already described in other writings. Accordingly, I go on to another and more difficult phase of thrombosis of the deep veins of the lower leg, namely, that which occurs during an illness, or postoperatively, or in the course of life in bed enforced by any posttraumatic state. Under these conditions, the patient being already horizontal and the femoral and iliac veins being unobstructed, *no swelling or cyanosis occurs*, and pain below the knee is slight or altogether absent.

Occurring During Life In Bed

Since thrombophlebitis occurring during life in bed causes few and unreliable subjective signs, it is often unnoticed until an embolism occurs. A sufficiently typical case will serve to describe it.

M. A. H., a 54-year-old woman, was operated on for gallstones and chronic cholecystitis. The operation and early days of convalescence were as uneventful as possible, but on the morning of the 8th day the patient complained of extreme shortness of breath and pain in the midchest. From this attack she recovered in the course of the day, the electrocardiogram showing no sign of coronary infarction.

Both lower limbs appeared completely normal: there was no cyanosis or swelling, and no tenderness. However, forced dorsiflexion of the feet brought out a *slight but* distinct discomfort in the back of the right upper calf. This was taken to be sufficient evidence of a deep throm-

bosis in some of the great venous plexuses of the calf—short perhaps of a venogram, which appeared dangerous under the circumstances.

Exploration of the femoral vein was made after the method presently to be described. When exposed, the superficial and common femoral veins appeared normal, but when the superficial femoral vein was opened, just distal to the profunda, there was found floating in the current the free proximal end of a thrombus, whose attachment must have been to a vessel in the upper calf or popliteal space. The upper part of this soft thrombus, from which the recent embolus is presumed to have broken, was sucked out, and the vein divided between ligatures. The patient made an uneventful recovery. The leg gave no trouble during convalescence or afterward.

That this sort of accident is not unusual requires no proof, although a warning embolism causing infarction does not by any means regularly precede the fatal breaking off of the long propagating thrombus. However, it is of some interest that, subsequently, this woman's brother, while under treatment for a neglected appendicitis, died of a pulmonary embolism. The autopsy disclosed the parent thrombosis in a plexus of veins between the gastrocnemius and soleus muscles, and a study of the lungs showed that a pulmonary infarction had preceded the fatal embolism. Possibly, a more suspicious and watchful attitude might have identified the warning infarct and even called attention to the guilty leg.

NONOBSTRUCTING BLAND THROMBOSIS IN THE UPPER FEMORAL AND ILIAC VEINS

Outspoken phlegmasia alba dolens, that is, the common milk-leg type of thrombophlebitis, is not the subject of these remarks. This disease fully occludes the great veins draining the leg, causes a considerable degree of edema, and if it were not a rather common cause of arterial or peripheral vasospasm and of disabling postphlebotic disorders, would be of little surgical interest. It is rather the nonobstructing thrombosis, forming the soft thrombus which sometimes fills the femoral and iliac veins, even floating up into the vena cava, that is in question here. In recent years, several German and French surgeons (Kulenkampff,⁴ Fründ,⁵ Låwen,⁶ Leriche⁷) have attacked such disorders without exactly defining them. But Låwen,^{8,9} in particular, distinguishes between bland thrombosis and an outspoken thrombophlebitis, the same distinction that I am making here. I think it probable that most of these processes originate in the lower leg—recent observations of Frykholm¹⁰ and others strongly support this contention—and that bland, nonobstructing femoral thrombosis has usually ascended from that region,* adhering to the vein here and there, and filling it loosely, without actually blocking it.

*In one case I actually watched a typical lower-leg deep thrombus, causing no swelling but a positive dorsiflexion sign, jump, as it were, and fully obstruct the upper femoral vein, producing swelling of the entire leg.

Such a thrombosis often, though not always, calls attention to the limb, even during life in bed, by some swelling and cyanosis below the knee. It is a source of repeated embolism, which ends, as a rule, in death. Pieces break off in the external or common iliac vein, until a considerable mass accumulates in the pulmonary vessels or until the detachment of an especially large mass ends the patient's life. Sometimes the process is bilateral, moderate swelling and blueness appearing only at one ankle, although quite as much thrombosis is present in the deep veins of the opposite limb.

Although both French and German surgeons have purposefully removed detachable thrombi from the common femoral and external iliac veins, —usually through an opening in the superficial femoral at the groin,—my own early experience followed the direction of an attempt to shut off the current and cause the process to become organized, until Dr. Arthur W. Allen demonstrated that through an opening in the common femoral vein, a huge mass of clot could be sucked out and the great veins safely cleared of thrombosed and clotted blood. I believe that in the future, instead of at once dividing the various femoral veins as he did, it might be permissible to repair the vein and institute for the next few days a vigorous heparinization. This step should safely restore, at least for the time being, the venous pathways, but whether it might not lead to a recurrence in the distant future is uncertain. At least, repair without division has safely been used* even before heparin was available.

The femoral vein at the groin should, then, be explored when, following a nonfatal embolism, evidence is secured that a nonobstructing or only partially obstructing thrombosis is present in the femoral and iliac veins. Through an opening in the superficial or perhaps the common femoral vein, the proximal and some of the distal part of the thrombus can be sucked out, and the accessible veins repaired or divided. Such a procedure is probably, in skilled hands, less hazardous than nonoperative treatment. I hardly dare put the matter more strongly.

EXPLORATION OF THE FEMORAL VEIN

The vessel may be approached by way of a long, oblique incision, parallel to the inguinal ligament (my own preference) or by a longitudinal incision, which must cross the ligament and be carried up on the abdominal wall.

The pulsation in the femoral artery is the guide to the situation of the vein, which lies medial to

it; and the saphenous vein, which should at first be preserved, leads the operator to the femoral vein itself. The soft tissues just lateral to the saphenous opening should be treated with respect, since they contain the lymph nodes so often inflamed in association with thrombosing processes in the leg.

Having demonstrated the saphenous opening and cleared the fascia lata below it, downward for 6 or 7 cm. and for perhaps 2 or 3 cm. above, one can easily expose a considerable stretch of the femoral vein. The vein and its branches must now be freed, so that short lengths of small, soft rubber tubing can be passed, respectively, about the common femoral vein above, the superficial femoral vein below, the profunda vein behind and the great saphenous vein in front. Since it is impossible to identify any but the most solid thrombus within the vein, the superficial femoral vein should now be incised longitudinally. The tubes control the bleeding.

Should an altogether loose clot be found, it is best sucked out. Good-sized glass tubing, having a smooth end, will do, but Dr. Allen demonstrated to me a good use for the Trendelenburg suction tube and reservoir, although it may be too large for the superficial femoral vein. What should one do if the thrombus seems rather adherent? The conservative surgeon will merely divide every vein and withdraw, as I have done.† The more radical surgeon will vigorously suck out the adherent thrombus, as I should feel justified in doing. He may then ligate and divide all veins or repair the opening in the femoral vein and heparinize the patient. During the convalescence, which, in case of division, may be attended by considerable edema and cyanosis of the leg, the foot of the bed should be raised 10 to 15 cm. above the head, and the leg left free for exercise. It should be recognized that whereas division of the superficial femoral vein for thrombosis confined to some group of deep veins below the knee is attended by little or no edema and cyanosis, the situation when the whole femoral system is occupied is very different; collateral pathways are perhaps involved, and division may cause serious edema.

EXPLORATION AND DIVISION OF THE FEMORAL AND ILIAC VEINS

For Recurrent Embolism

Recurrent embolisms are commoner than one would suppose. I have recently encountered four such cases. They are likely to be picked up by the cardiologist, since they are readily mistaken

*In 1926, Bazy¹¹ removed a soft thrombus from the axillary vein, which he reported, in a case of *thrombose par effort*. Edema soon receded, and the patient recovered. Other similar experiences have been recorded, and many, perhaps, have never been published. But fatalities as well have occurred (see discussion of Kutenkampff's¹² communication).

†In one such case, embolism recurred, and I was finally obliged to divide the common iliac vein, embolism ceased, and the leg has become functionally useful.

for cases of myocardial infarction due to coronary disease. A study of the problem of repeated embolism is a fascinating one, and I² have already

dolens, which, though of itself an uncommon source of embolism, may lead to a local recurrent thrombosis and subsequent embolism; a previous

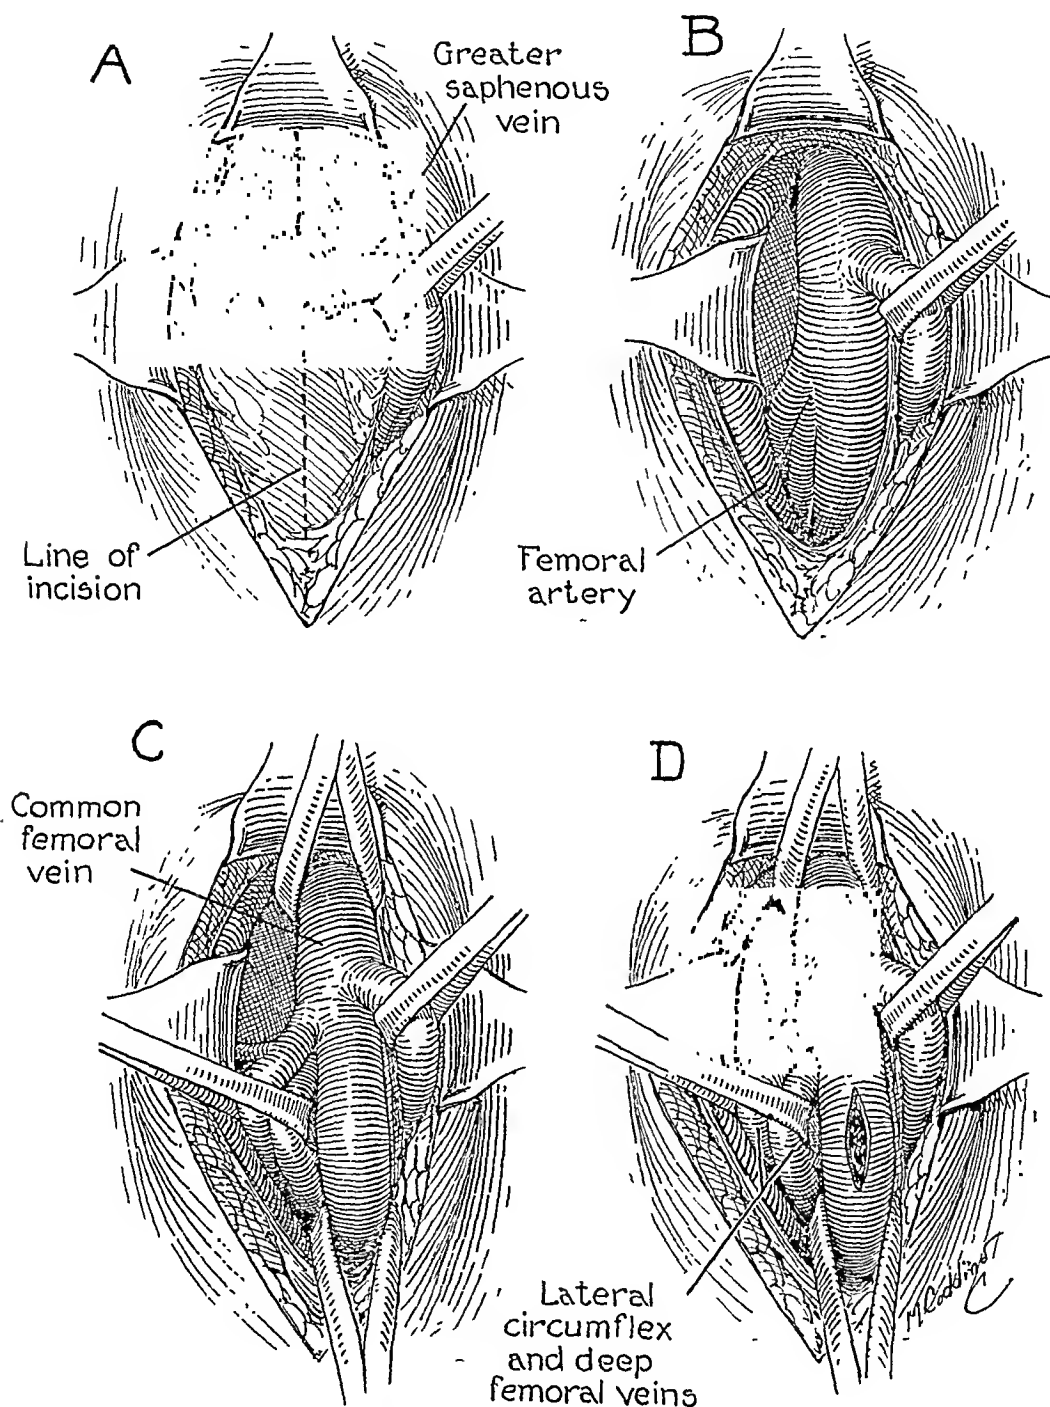

FIGURE 1. *Semidiagrammatic Sketch Demonstrating Exploration of the Right Femoral Vein.*

A. Incision at the groin exposing the saphenous opening; site of incision of deep fascia.
 B. The common femoral vein and its branches; the femoral artery is retracted laterally.
 C. Soft tubing is placed around the various veins. D. As the tightened tubes control bleeding, the superficial vein is opened, revealing a thrombus.

published the details of a number of these cases.

The history is most important. Is there a story consistent with an earlier thrombophlebitis? This may take the form of a typical phlegmasia alba

nonobstructing thrombosis in the lower leg or higher, associated with embolism; or a superficial thrombophlebitis, in the saphenous system, for instance, perhaps in a varicose vein, from which

small emboli may have been detached, or which may have extruded a propagating thrombus into the femoral.

It is in running down an earlier thrombophlebitis that a venogram may be remarkably useful (Dougherty and Homans¹²). It may be possible to show that the femoral vein is of irregular caliber and without valves, owing to previous disease. In a case of this sort—that of a man condemned to invalidism because of supposed coronary disease—I found, on transperitoneal exploration, the left external iliac vein adherent to the artery and partly filled with fibrous ribbons left by canalization of the old process. Division of the vein has for over two years prevented recurrence of the former minor embolisms.

In other cases, following a story of old thrombosis and embolism, it has seemed best to operate immediately after the most recent episode, provided the same leg as before has clearly been affected, since, at this moment, exploration of the femoral region may demonstrate, more accurately than at any other time, the situation of the process. For example, exploration may reveal that this is and has been altogether below the groin, or perhaps in the great saphenous vein. If sclerosis and adhesion of the common femoral vein behind the inguinal ligament show that the process has extended higher, the choice is given of dividing the superficial femoral vein, on the ground that blocking this now valveless and sclerosed vessel will prevent further recurrence of the thrombosis, or of exploring retroperitoneally or transperitoneally the iliac veins and dividing the external or common iliac vein. I can only hint at some of the possibilities in this fascinating field. The most satisfactory aspect of proximal division to forestall further embolism is that such division appears to have a favorable effect on the peripheral circulation; that is, a collateral circulation having already been established, little cyanosis or additional swelling follows. The foot is apt to feel warmer, and the leg is afterward the source of fewer discomforts. This favorable effect may be due to the prevention of reflexly excited vasospasm and to the relief of back pressure in a valveless vein. To say that in any one case the operation has guaranteed the patient against embolism is, of course, unjustified, even after the flight of considerable time.

To Relieve Local Arterial Or Peripheral Vasospasm

Exploration to relieve vasospasm is, of course, a field as to which little is known. Actually, any one of three types of vasospasm may be associated with a femoroiliac thrombophlebitis. The first is the diffuse peripheral type, thought to occur principally in the venules just beyond the capillary

bed; this is believed to be an important cause of the edema of phlegmasia alba dolens, and according to Leriche and Geisendorf,¹³ Ochsner and DeBakey^{14,15} and others, is relieved by sympathetic lumbar procaine block. I am inclined to agree that lumbar block does in some degree release such vasospasm. In any case, exploration is not demanded.

The second variety of vasospasm is represented by a sudden constriction of the great artery accompanying the thrombosed vein. This is a rare event, but serious. It shuts off, or nearly shuts off, the arterial supply to the limb, and may actually lead to gangrene. Explorations have disclosed the contracted, threadlike artery but have accomplished little. I myself have seen such spasm disappear after an effective lumbar sympathetic block. It is quite capable of relaxing spontaneously—and unpredictably.

The third variety is the late, diffuse peripheral spasm, related to the early acute type, which may remain for years after an initial femoroiliac thrombophlebitis has subsided. This is probably due to fibrosis of the wall of the great vein and to an irritation of perivascular nerves, sensory or vasomotor or both. Its effect is causalgia-like; that is, the limb is slightly cyanotic, edematous and oversensitive to pinprick and pressure. Confirmation of a tentative diagnosis is secured by noting the immediate temporary relief obtained by a lumbar sympathetic procaine block. Such an effect may even, in mild cases, be prolonged by repeated lumbar injections until it has become a cure. Sympathectomy relieves with even more certainty, but there may also be an advantage in dissecting apart the great iliac and femoral vessels and even in dividing the great vein. This is Leriche's particular contribution. Naturally, the operation requires considerable skill and familiarity with the handling of large blood vessels. I believe that the right iliac vessels should be approached extraperitoneally; the left, transperitoneally.

DIVISION OF THE FEMORAL OR ILIAC VEINS FOLLOWING AN OLD THROMBOPHLEBITIS TO PREVENT BACKFLOW

I have several times remarked on the apparent harmlessness and even benefit to the circulation of high division of such femoral or iliac veins as have previously been the seat of thrombophlebitis. I hardly care to go farther into this subject here. Obviously, the femoral system, once thrombosed, must suffer the loss of all its valves (there is rarely one in the external iliac vein and none above), so that when the body is erect, the venous return must take collateral, valved pathways. Blood must pour down a valveless vein, and it is

therefore reasonable to assume that an old, sclerosed, canalized femoral or external iliac vein is better divided. I have never performed division of such a vein for back pressure alone, not fully understanding the indications, but I am sure that the procedure—barring the risk of any such operation in patients of middle age or beyond—will always do good, and never harm.

SUMMARY AND CONCLUSIONS

Evidence has been produced to show that bland, nonobstructing thrombosis of the leg, whether occurring in active life or life in bed, and whether confined to the venous plexuses among the muscles below the knee or occupying as well the femoral and even iliac veins, is a frequent source of pulmonary embolism. This type of thrombosis, though difficult of identification, can often be diagnosed, whether or not embolism has occurred, by a combination of clinical symptoms with discomfort behind the knee on forced dorsiflexion of the foot. Conservative treatment of this disorder is usually justified, but when embolism has occurred or when symptoms and signs have recurred at least once, exploration and division of the femoral vein are advisable.

Exploration and division of the femoral and iliac veins may also be indicated to cure peripheral vasospasm, especially when the vein has been the seat of previous thrombophlebitis, and to guard against the further recurrence of pulmonary embolism repeated once or more.

Division of the superficial femoral vein, in the presence of a bland, nonobstructing thrombosis below the knee, is rapidly curative and leads to no swelling and cyanosis of the leg. Division of the common femoral and profunda veins for a bland, nonobstructive thrombosis that occupies the femoral vein itself causes considerable edema and cyanosis.

Division of the superficial femoral, common femoral or even common iliac vein, following an old, canalized thrombophlebitis, causes little disturbance and may, by relief of reflex vasospasm and by the prevention of backflow in the vessel, be of benefit to the venous circulation.

DISCUSSION

DR. HENRY H. FAXON, Boston: Our active interest in this type of operation at the Massachusetts General Hospital goes back only a few years, and it is characteristic of Dr. Homans's enthusiasm in this field that he was doing some such operation many years ago.

In my discussion of his paper I shall confine myself to the operation as it relates to the prevention of emboli. I should like to make three points and possibly ask one question.

The first point, it seems to me, is of fundamental importance in a consideration of this whole problem, and Dr. Homans has not been perhaps too explicit concerning it. Specifically we should like to know, in a patient with a deep phlebitis, what are the chances of his getting an infarct, and what are the chances of his getting a fatal pulmonary embolus. The operation mentioned by Dr. Homans is not without a certain amount of risk, and to evaluate the urgency for doing it, one should know what chance the patient runs of having a serious catastrophe if the operation is not performed.

Dr. Welch and I, at the Massachusetts General Hospital, have reviewed the cases of clinical phlebitis and pulmonary embolus in the last few years. From this study we have come to believe that if a patient has a deep phlebitis in an extremity, he stands one chance out of three of having a pulmonary infarct, and one out of twenty-five of having a fatal massive embolus.

We do not know yet, because we have not done enough operations, how great is the risk of the procedure suggested by Dr. Homans. The risk is small, I am ready to admit. We have done about twelve of these operations with certain modifications of the technic outlined by Dr. Homans. We have had no fatality at the hospital. I have had one fatality in a patient at an outside hospital, who was operated on when she was in extremis. She had a high temperature, had had multiple infarcts and was obviously going to die if nothing was attempted, and she did die following exploration of the femoral vein.

My second point, one on which he laid very little stress, and one that I consider very important, is that the age of the patient makes a great deal of difference as to whether or not this operation should be carried out.

In looking over the cases of deep phlebitis at the hospital, it was interesting to note that if the patient was under fifty years of age, the chance of his having a fatal massive pulmonary embolus was very small. Less than 2 per cent of the cases under the age of fifty had a massive pulmonary embolus from a demonstrable, clinical phlebitis. On the other hand, when the people with deep

phlebitis were between the ages of fifty and sixty, about 7 per cent suffered a massive embolus, and in the small group of patients over sixty who had deep phlebitis, nearly 20 per cent had a massive fatal embolus.

It is our belief at the present time, and it is subject to revision, that we should be strongly tempted, in a case of deep phlebitis under the age of fifty, to treat the patient conservatively with the measures we already know, including the use of heparin. When we consider patients who are older, the urge to do this operation, in our minds, becomes progressively greater.

The third point I should like to make is to stress again what Dr Homans has suggested, namely, that the problem of massive pulmonary embolus is by no means synonymous with that of demonstrable clinical phlebitis. In the last few years we have had 128 cases of massive pulmonary embolus, and in less than 6 per cent was there in the record any suggestion of a deep phlebitis. It is true, probably, that if the examination of those patients had been carried out more carefully many of them would have been found to have had definite or suggestive signs of deep phlebitis.

The question I should like to ask Dr Homans is, Why, when he believes that most of these emboli come from the popliteal space or the venous plexus in the calf of the leg and that the valves of the deep system are extensively damaged following a deep phlebitic process,—an assumption that I question,—should he ever suggest opening the vein, aspirating the clot, and then suturing that opening in the vein and heparinizing the patient? I think that if an operative procedure is indicated, one should certainly put a dam across that femoral vein so that an embolus from the lower portion of the extremity could not possibly become dislodged and give the case a fatal outcome. In other words, one may open a certain number of femoral veins and find no clot, or one may open a certain number and aspirate a clot, but in either event there is no definite assurance that there is no additional clot in the region of the popliteal space or calf muscles that may still be a menace to the patient if the continuity of the vein is not interrupted in some way.

DR EUGENE E O'NEIL, Boston. Anyone who has seen a patient die of pulmonary embolism due to a known lower leg thrombosis must be impressed by the necessity of doing a femorofemoral vein ligation.

My attention was called to the urgency of this procedure some years ago in a woman whom I had discharged three months after an original trauma to the lower leg, and in whom I had made a diagnosis of thrombosis of the posterior tibial veins. I mention this because it brought home to me with a shock something that I had not appreciated before, namely, that people can have propagating clots in their venous systems for a very long time, and that these clots can become detached and cause sudden death. This particular case was proved at autopsy. Since that time I have explored and ligated 20 cases.

I concur in what Dr Faxon has said about the age limits for this group. Eighteen of my patients were over the age of fifty-five. I had an impression in reading the original paper that Dr Homans sent to me that he was somewhat emphatic in stating that this operation should be used only in the young and middle-aged groups. Perhaps my conception of middle age will change as I grow a bit older.

I might add that all these cases have been operated on in accordance with the indications that Dr Homans has laid down, and that I am quite in agreement with them. The technic does not differ materially from his, except that I believe that the majority of these cases can be ap-

proached below the inguinal ligament through the superficial femoral vein. Although I have used off four external iliac veins and two common iliac veins, at the present time I think that most of these thrombi can be approached through the superficial femoral vein, and the clot removed, with little likelihood of a fatality.

Concerning the tying off of the femoral vein for recurrent emboli and recurrent phlebitis, my experience is confined to a single case. In cases of acute phlebitis in various veins, as well as recurrent phlebitis, the quickest way to stop the phlebitis is to do an immediate ligation. I should like to make a plea here that in all these cases of acute phlebitis in superficial veins, an immediate ligation be done. I am sure that that will get the patient back to normal much more quickly than any other method. If this is so, it seems to me that the application of that principle to the deep vein is sound.

One more thought concerning these cases of chronic vasospasm, which manifest these causalgia-like signs and symptoms. Since I have had no experience with exploring these veins for that condition, I should consider a lumbar sympathectomy not only to be technically easier but also, perhaps, to result in more permanent effects. Certainly in my hands the operation for lumbar sympathectomy in these cases has given extremely satisfactory results, more so, probably, than any other condition for which I have done sympathectomies.

The problem that Dr Homans has presented is a very important and fascinating one. If we remember to look at our patients' legs occasionally, post partum or post operatively, or following trauma, I think that we shall be exploring these veins oftener, and occasionally saving a life.

DR FRANK R OBER, Boston. In some prolonged cases of synovitis of the knee, so-called water on the knee, in which an associated swelling of the calf has not responded to treatment, the diagnosis of phlebitis must be considered.

A few years ago a colleague of Dr Homans and mine had an attack of synovitis of the knee that did not respond to treatment. This man died very suddenly from pulmonary embolus, as the autopsy revealed. It is such cases that usually come to the orthopedic surgeon, who is apt to think in terms of joints. I think it behooves us to think also of the joint in terms of circulation. Treatment of synovitis of the knee is a relatively simple problem, but all of us should be on the alert in making the diagnosis to inspect the circulatory system as well as the knee, because we may thus obtain additional information that has a direct bearing on the joint affection.

DR HOMANS (closing). I have been very much enlightened by this discussion.

Dr Faxon asks why, having opened a vein, one should ever close the opening and heparinize. I was thinking of the cases in which the thrombosis has occurred above the point where the vein is conveniently opened. All explorations must be made, practically, through the groin; there may be thrombosis above that point, and it does little good to divide the superficial femoral vein alone, since plenty of current comes from the various branches that enter the common femoral and external iliac veins. It was in relation to that that I considered the possibility of heparinization and closure of the opening.

Of course, for all thromboses below the groin I think the vein ought to be divided. I am sure that the vein ought never to be closed and heparinized in such cases.

When I heard Dr O'Neil use the word "ligate," it excited me, as it always does, because I think one should not speak of ligating a vessel. You cannot divide a vessel without ligating, but if you ligate it alone, you do not

do the same thing as if you divide it. I think we have used the word loosely. Dr. O'Neil really means "divide," or even "resect."

In respect to Dr. O'Neil's remarks about the relief of peripheral vasospasm by sympathectomy rather than by exploring the vein itself, I am inclined to agree with him, but I have been trying to learn something about the subject by exploring the vessels themselves, and in one or two cases I have relieved peripheral spasm by dividing the vein where there was an obvious thickening of its wall, so that sympathectomy has not been required.

I was interested in what Dr. Faxon had to say about percentages of infarction and embolism, which is very much worth considering. All that I have said on the subject really has back of it the idea that one should have no accidents following the operations I have recommended and that one should therefore do better than Nature will alone. That one can perform these operations without any accidents or with fewer accidents in the way of embolism than when no operation is used, is not yet clearly proved, but I think that the procedures are safe.

As to the age of the patient, I believe I agree entirely. I have been using division of the vein for two purposes. One was to cure the disease, and the other was to prevent

embolism. Division of the vein in thrombosis below the knee cures the disease very rapidly, and although I am sure that these young people may suffer embolism, they seldom actually do so. On the other hand, the disease is very rapidly cured.

In respect to the disease that begins below the knee,—the quiet disease, the source of the fatal embolism,—I have learned from Dr. John Sears that he sees more cases with outspoken symptoms than I do. He showed me a case this summer of a patient with a tender calf, slight swelling and real pain. I have been assuming always that patients whose thrombosis takes place among the muscles of the calf show almost no symptoms, and I have taken it for granted that the more symptoms the patient exhibits, the more inflammatory is the disease, and the less the chance of embolism. Whether that is a proper point of view, I do not know. On the whole I think it is, but I know that Dr. Sears has been dividing these femoral veins in cases in which the patient's symptoms have been outspoken, and yet the thrombosis has been proved, on the operating table, to be of the lower-leg rather than the femoroiliac type.

I am very much obliged for the discussion, but I should have been more obliged to the discussers if they had not taught me quite so much.

SARCOIDOSIS WITH BRONCHIAL INVOLVEMENT*

Report of a Case with Bronchoscopic and Pathological Observations

EDWARD B. BENEDICT, M.D.,† AND BENJAMIN CASTLEMAN, M.D.‡

BOSTON

SARCOIDOSIS, or Hutchinson-Boeck's disease, is a generalized systemic disease that, according to Hunter,¹ may involve, in addition to the skin, the lymph nodes, spleen, lungs, bones, mucous membranes, conjunctivas and parotid glands. The histology of the lesions resembles that of tuberculosis except that no caseation is observed and no tubercle bacilli are found, even by guinea-pig inoculation. The disease has been frequently reported involving the lungs and tracheobronchial lymph nodes, but so far as we have observed it has not been reported clinically in the tracheobronchial tree. Snapper,² however, states that Boeck reported sarcoid occurring in the bronchus. After looking through the original articles of Boeck to which Snapper refers, we have been unable to confirm this. In 1929 Bernstein, Konzle-mann and Sidlick³ reported a case of Boeck's sarcoid with involvement of the bronchial mucosa. Clinically their patient showed a bilateral hydrothorax, with severe dyspnea. There was no wheeze, no bronchoscopy was performed, and no clinical diagnosis of bronchial sarcoid was made. At

autopsy the bronchial lesion was represented by small hemorrhagic patches. From microscopic examination these authors concluded that the lesion in the bronchiole was an extension from the adventitia of an associated arteriole. Opsahl⁴ recently reported a case of bronchial obstruction caused by a mass that, when removed bronchoscopically, had the characteristic histology of sarcoid. In that case, however, tubercle bacilli were found histologically and by guinea-pig inoculation. It therefore appears that he was dealing with tuberculous tracheobronchitis and not with sarcoid. Spencer and Warren⁵ reported autopsy findings in a case of sarcoid in which the trachea showed numerous lesions both immediately beneath the mucosa and among the mucous glands, where there was considerable distortion, fibrosis, round-cell infiltration and degeneration. In their case the bronchi were normal, and the tracheal lesions submucosal.

The following case is, we believe, the first to be reported of definitely intrabronchial sarcoid lesions in which the diagnosis was made by bronchoscopy.

CASE REPORT

R. C. (M. G. H. No. 165665), a 20-year-old Negress, first entered the hospital on December 20, 1938, complaining of

*From the Massachusetts General Hospital.

†Assistant in surgery, Harvard Medical School; assistant surgeon, Massachusetts General Hospital.

‡Instructor in pathology, Harvard Medical School; assistant pathologist, Massachusetts General Hospital.

cough. She had been well until 1 year before admission, when she developed a cough not associated with sputum or chest pain. For 6 months she had experienced weekly

2 or 3 cm. in diameter. The temperature varied from 98 to 102°F., the pulse from 80 to 120, and the respirations from 20 to 30.

The urine showed the slightest possible trace of albumin. The red-cell count was 4,500,000, and the white-cell count 5,150,000, with 56 per cent polymorphonuclears, 29 per cent lymphocytes, 10 per cent monocytes, 3 per cent eosinophils and 2 per cent basophils. The platelets were normal; the red cells showed slight hypochromia. A tuberculin test with a 1:10,000 dilution was negative. A blood Hinton test was negative.

X-ray examination of the chest showed clear lung fields. There was widening of the superior mediastinum anteriorly, more marked on the right, which was interpreted as enlarged lymph nodes consistent with mediastinal lymphoma. There was no evidence of widening of the carina. The trachea and esophagus were not displaced. The hands and feet were normal.

The right supraclavicular lymph node was removed, and when examined microscopically showed complete replacement of the lymphoid tissue by well-circumscribed tubercles composed of epithelioid cells, with an occasional Langerhans giant cell but without any caseation—a picture characteristic of sarcoid. A stain for tubercle bacilli was negative. The patient was discharged on the 11th day to a convalescent home.

The second admission took place 2 months later. At this time the patient complained of continuous sharp pain in the right flank and right shoulder, with pain on coughing or deep breathing. Physical examination showed several pea-sized lumps under the skin in the right chin, right forearm, right 12th rib posteriorly and left 2nd rib

FIGURE 1. *Bronchoscopic View at the Carina in Sarcoidosis.*

Note the widening of the carina and the intrinsic bleb-like lesions on walls of both the main bronchi.

night sweats, and she had lost some weight. Two months before entry the cough was productive of whitish phlegm, and a mass was noted in the right supraclavicular region. The past and family histories were noncontributory.

Physical examination showed a well developed and well-

FIGURE 2. *Photomicrograph of One of the Bronchial Biopsy Specimens.*

This shows several sarcoid lesions in the region of a group of mucous glands.

nourished colored woman in no pain or discomfort. The only positive findings were palpable, nontender cervical, inguinal and right supraclavicular lymph nodes, measuring

anteriorly. Tuberculin tests with 1:5000, 1:1000 and 1:100 dilutions were negative. A biopsy of a subcutaneous nodule in the right flank was reported as consistent with sarcoid.

The temperature varied from 98 to 99°F., the pulse from 70 to 90; and the respirations were 20. Examination of the sputum was negative for tubercle bacilli.

After 2 weeks in the hospital the patient was discharged to a convalescent home, where a regimen of rest and high-vitamin diet produced definite improvement. Two months later it was noted that the lymph nodes in the right lower neck seemed a little smaller and softer. Moist sibilant and sonorous rales were heard in the chest on both sides. A skin lesion appeared on the left cheek.

The third admission occurred 8 months later, in January, 1940. During the month before entry, it was noted that the patient was getting worse, had been wheezing and

and reddened throughout, and the lumen markedly narrowed, so much so that the No. 7 bronchoscope would not pass into the right lower lobe. None of the orifices could be seen because of edema of the mucosa. Soft esophageal bougies Nos. 12 to 16 passed satisfactorily into the lower lobe. Because of dyspnea during bronchoscopy, oxygen was administered through the bronchoscope, with marked improvement. The left bronchial tree showed an appearance similar to that at the right, with red edematous mucosa and bleb-like formation. The orifices could not be seen because of edema. A No. 16 bougie was passed into the left lower lobe. The conclusions from bronchoscopy were as follows: definite reddening and edema with bleb-like

FIGURE 3. Photomicrograph of a Cervical Lymph Node.

This shows complete replacement of the lymphoid tissue by sarcoid, tubercle-like nodules.

was feeling too sick to work. There was marked generalized lymphadenopathy, especially in the cervical, preauricular and submental regions. Large "furniture-moving" rales were heard throughout the chest. X-ray examination of the chest showed a marked decrease of the mediastinal mass, particularly on the right. The lung fields were clear.

At this time the chief problem was respiratory difficulty suggestive of partial tracheal or bronchial obstruction. The picture clinically was that of asthma, with universal wheezing and rhonchi. In view of these findings and the possibility of tuberculous tracheobronchitis, bronchoscopy was suggested, although the patient seemed rather ill and many of the staff were unenthusiastic.

Bronchoscopy was carried out on February 9. The positive findings were as follows: The mucosa of the trachea was somewhat reddened and edematous. The carina showed definite reddening and thickening, with yellowish bleb-like lesions 2 or 3 mm. in diameter (Fig. 1). The right bronchial tree showed the mucosa to be edematous

formations through the entire bronchial tree, and marked narrowing of the main bronchi, accounting for wheeze and dyspnea. Several biopsy specimens were taken from these lesions and showed replacement of the mucosa by an edematous inflammatory reaction composed of lymphocytes and a few polymorphonuclears. Scattered through this tissue were many tubercle-like lesions composed of epithelioid cells with giant cells—an appearance consistent with sarcoid (Fig. 2). Biopsy specimens from another cervical lymph node (Fig. 3) and from a skin lesion in the region of the temple showed a characteristic sarcoid appearance. A smear from material obtained at bronchoscopy showed no tubercle bacilli, and guinea-pig inoculation was negative for tuberculosis. Guinea-pig inoculation of a biopsied lymph node showed no tuberculosis. Repeated examinations of the sputum for tuberculosis were negative. A tuberculin test with a 1:100 dilution was again negative.

On the day after bronchoscopy, the patient was notably better and without wheeze. There was also definitely less cough and dyspnea. Five days following bronchoscopy,

however, there was an increase in wheezing. Ten days later, therefore, bronchoscopy was repeated. At this examination the mucosa showed improvement. There seemed to be fewer lesions, which were pearly gray and almost cystic at the carina. Along the wall of the left main bronchus the appearance was that of whitish, fibrous stenosis with definite narrowing of the lumen. Bougies up to No 20 were passed into both lower lobe bronchi, and 20 per cent cocaine-adrenalin was applied. A moderate amount of secretion was aspirated. Except for a temperature rise to 104°F, a week after the second bronchoscopy, thought to be due to an attack of grippe, convalescence was uneventful. The patient was discharged improved to a convalescent home on March 25.

She was last seen in the Pulmonary Clinic of the Out Patient Department on October 16, at which time she had no complaints, was feeling very well and was able to do housework. There was less dyspnea, no wheezing and very little cough or sputum. The appetite was very much improved, and the lymph nodes were much smaller.

SUMMARY

A case of generalized sarcoidosis is reported in which signs and symptoms of bronchial obstruction

were the principal features. Bronchoscopy showed extensive intrinsic involvement of the bronchial mucosa, and treatment through the bronchoscope resulted in marked clinical improvement.

So far as we have been able to determine, this is the first reported case of sarcoidosis with intra-bronchial lesions in which a positive diagnosis was made by bronchoscopy.

PERIPHERAL ARTERIAL EMBOLISM*

A Discussion of the Postembolic Vascular Changes and Their Relation to the Restoration of Circulation in Peripheral Embolism

ROBERT R. LINTON, M.D.

BROOKLINE

THE successful restoration of the circulation in a limb following peripheral embolism depends chiefly on early and adequate treatment. All writers on the subject stress the importance of this fact. Thus, in a series of 282 cases collected from the literature, Pearse¹ found that when embolectomy was performed within ten hours of lodgment of the embolus, the extremities were saved in 40 per cent of the cases; after ten to fifteen hours, in only 16 per cent; and after thirty hours, in none. In a series of 129 cases reported by Danzis,² 47 patients were operated on within eight hours, and in 27 cases (57 per cent) the circulation was restored; in 24 cases operated on between eight and twelve hours after lodgment, it was restored in only 6 (25 per cent). Similar statistics are given by Key,³ Petitpierre⁴ and Dschanelidze and Ogloblina.⁵ Early treatment is of equal importance when cases are treated with the negative positive pressure (pavey) apparatus, as was shown by me⁶ in a series of 13 cases. In this group, 9 (60 per cent) of 15 extremities were saved; the

treatment was instituted within ten hours in 8 (90 per cent) of these.

The commonest cause of gangrene following peripheral embolism is the failure to institute adequate treatment before the arteries distal to the embolus have been irreparably damaged. It is rarely the result of poor surgery or inadequate treatment. Thus the loss of a limb is directly attributable to the failure of the physician who first sees the patient either to make a correct diagnosis or to realize the imperativeness of early treatment. Since the diagnosis of arterial embolism has been discussed adequately by Pearse,¹ Danzis,² Key,³ McKechnie and Allen,⁷ Allen⁸ and others, it is not necessary to consider this phase of the subject. On the other hand, very little has been written concerning the pathologic changes that take place in the arteries of an extremity following the lodgment of an embolus, and the significance of these changes in reference to restoration of the circulation.

The purpose of this paper is to emphasize the importance of early adequate treatment in arterial embolism by discussing the postembolic arterial

*From the Peripheral Vascular Clinic, Massachusetts General Hospital. Instructor in surgery, Harvard Medical School; assistant surgeon, Massachusetts General Hospital.

changes in a group of selected cases of peripheral embolism treated in the Peripheral Vascular Clinic of the Massachusetts General Hospital. In some of these cases there was a successful restoration of circulation, whereas in others gangrene developed.

Failure to restore the circulation in an extremity following embolism is due primarily to the marked vasoconstriction distal to the embolus, and the formation of a secondary thrombus in the arterial tree that extends distally from the site of embolism into all the tributaries and finer ramifications. The marked spasm of the arteries has been recognized for many years. It has been described by Seifert⁹ and observed by many surgeons who have performed embolectomies. The secondary thrombosis has also been described by Nyström,¹⁰ Zierold¹¹ and other authorities, but its role in the results obtained has not been sufficiently stressed in the literature. This secondary thrombus, if it forms, makes the difference between success or failure in the restoration of the circulation. It undoubtedly develops as a result of the extreme degree of vasoconstriction and slowing of the blood stream, which occurs distal to the site of embolism, since the marked narrowing of the main and the collateral arteries, in addition to the obstruction by the embolus, causes practically a cessation of the arterial inflow to the extremity. This leads to stagnation of the blood in the involved arteries, which later clots to form the thrombus. Whether thrombosis begins at the most distal portion of the extremity and extends upward, or just distal to the embolus, as a result of the irritation to the intima, has not been established.

The constriction of the artery distal to the embolus, which probably occurs almost instantaneously after the lodgment of the embolus, is followed in a few hours by the development of complete thrombosis of the artery. In one of the cases reported in this article, an extreme degree of arterial spasm was noted one and a half hours after the time of embolism, and in another case, a very extensive thrombosis had formed nine hours after the time of embolism. The ideal treatment to restore the circulation of an extremity, following the lodgment of an embolus, is to remove it as soon as possible. In addition, treatment should be instituted to prevent the formation of a secondary thrombus, since this may occur even after embolectomy, owing to damage of the intima, from both the operation and the impaction of the embolus. This treatment should be directed toward the production of peripheral vasodilatation to increase the arterial inflow to the extremity. One method of doing this is to interrupt the sym-

thetic vasoconstrictor impulses by a novocain or alcohol injection of the lumbar ganglia. Another is by mechanical dilatation, using intermittent suction and pressure (pavex) or intermittent venous occlusion. The intravenous injection of heparin may also be used to prevent the formation of the secondary thrombus. To emphasize the role of vasoconstriction and secondary thrombus formation, the following cases are presented.

CASE REPORTS

CASE 1. A 54-year-old man with rheumatic heart disease and auricular fibrillation suddenly developed pain and numbness of the left arm. Examination revealed that there were no pulsations below the axillary artery. An operation was performed 1½ hours after the occurrence of the embolism, and an embolus was removed from the left axillary artery. At operation, marked constriction of the artery to about one third its normal caliber was noted

FIGURE 1.

This photograph shows the embolus removed from the left axillary artery in Case 1, one and a half hours from the time of embolism. It should be noted that this specimen consists only of the embolus, without any evidence of a secondary thrombus.

distal to the embolus. There was practically no vasoconstriction above the site of embolism. After removal of the embolus, with the artery occluded proximal to the opening, there was an excellent flow of blood from it, indicating that the collateral arterial blood channels were patent and that there was no secondary thrombus in the arterial tree distal to the site of embolism. As further evidence of this, there was an immediate restoration of the circulation following suture of the arteriotomy wound, and in addition, examination of the specimen revealed it to be a single homogeneous blood clot (Fig. 1).

CASE 2. A 45-year-old man with rheumatic heart disease and auricular fibrillation suddenly developed pain and numbness of the left leg. Examination showed no pulsations in any of the arteries of this extremity. They were normal in the right leg. A diagnosis was made of an embolus lodged at the bifurcation of the left common iliac artery. Two and a half hours after the time of

embolism, an embolus was removed from this artery. The operative findings are shown in Figure 2. The extreme narrowing of both the external and internal iliac arteries distal to the embolus should be noted. At operation this constriction extended as far as the vessels could be traced distally, that is, down to the inguinal ligament and into

FIGURE 2.

This drawing shows the transabdominal operative exposure for embolism of the left common iliac artery used in Case 2. This exposure was made within two and a half hours after the lodgment of the embolus. The marked narrowing of the external and the internal iliac arteries should be noted. This extended distally as far as the arteries could be traced. The constriction of the common iliac artery proximal to the embolus, on the other hand, is seen to be present over a very short distance. The incision made in the artery to remove the embolus is shown.

the pelvis, a distance of several centimeters. The common iliac artery above the embolus was also narrowed, but of utmost importance was the fact that contrary to the constriction distalward, it was very sharply localized, so as to involve less than a centimeter of the artery. Above this point the artery was of normal caliber. The embolus removed is shown in Figure 3. At operation there was no evidence of a secondary thrombus distal to the embolus, in either the internal or the external iliac arteries. There was profuse back bleeding when the tourniquets on these vessels were released. In addition, after the operation was concluded, it was possible to palpate the pulsations in the popliteal artery, the dorsalis pedis and the posterior tibial arteries. This was positive evidence that there had been a complete re-establishment of the arterial circulation, and that a secondary thrombus had not formed within 2½ hours of the time of embolism.

In the two following cases the arterial circulation was not restored following embolectomy; the result in both was gangrene, necessitating amputation

CASE 3. A 55-year-old woman with rheumatic heart disease and auricular fibrillation had been in the hospital for 10 days, when she was suddenly seized with severe pain and numbness in the right leg. A diagnosis of peripheral embolism of the right common femoral artery was not made until 8 hours later. The embolus (Fig. 4) was removed approximately 9 hours after the onset of symptoms.

With these facts in mind, a careful examination of the specimen yielded some highly valuable information. The embolus consisted of two parts, a short, thick one, and a long, narrow one. The former was grayish pink and quite firm in consistence, whereas the latter was dark reddish brown and very friable. The thicker portion represents the embolus, the narrow portion a secondary thrombus, which had formed after lodgment of the embolus. The embolus was lodged at the bifurcation of the common femoral artery and the thrombus was found to be

FIGURE 3.

This is a photograph of the embolus removed from the left common iliac artery at its bifurcation into the external and internal iliac arteries in Case 2. The operation was done two and a half hours after the lodgment of the embolus. The main part of the embolus lay in the common iliac artery. The two projections on the specimen represent the portions of the embolus that were in the external and internal iliac arteries. The diameter of these indicates the marked constriction of the arteries. The absence of any secondary thrombus should be noted.

lying distal to it. The difference in the diameter of the two should be noted. The embolus was several times greater in caliber than the secondary thrombus. Despite this fact, each completely filled the artery in which it was lodged. Thus examination of this specimen showed clearly the marked degree of arterial constriction that takes place distal to the site of embolism.

The removal of the embolus was a relatively simple matter, but the secondary thrombus was removed with great difficulty. The only satisfactory method of extracting it was by milking the vessel upward, and even then it was impossible to ascertain if all of it had been obtained. Of great significance was the fact that there was very little bleeding from the distal part of the femoral artery after the removal of this specimen, which indicated that it

had not been completely removed. This was further substantiated immediately after the operation by the lack of pulsation in the popliteal, dorsalis pedis and posterior tibial arteries. Gangrene developed in the foot and lower leg within 24 hours, necessitating a mid-thigh amputation.

CASE 4. A 61-year-old man who had coronary heart disease developed an embolism of the left popliteal artery,

caliber as the embolus, was the proximal secondary thrombus. The two thrombi were about the same length. It is to be noted, however, that the proximal one is shown in its entirety, whereas only a small portion of the distal one can be seen in the photograph. There can be little doubt of these facts, because on removal of the embolus and the proximal thrombus there was a tremendous spurt of arterial blood from the upper end of the incision in the popliteal

FIGURE 4.

This photograph shows the embolus and a portion of the secondary thrombus that had formed distal to the embolus from the femoral artery in Case 3. The specimen was removed from the common femoral and the superficial femoral arteries nine hours after the time of embolism. The portion with greatest diameter represents the embolus and the long narrow portion, the secondary thrombus. The small caliber of the latter indicates the marked constriction that was present in the arteries distal to the embolus.

and operation was performed 72 hours after its occurrence. The embolus and a portion of a secondary thrombus were removed, but gangrene of the foot developed, necessitating amputation of the leg.

Examination of the specimen (Fig. 5) showed it to

artery, yet there was no bleeding from the lower end. In addition, the posterior tibial artery was exposed behind the medial malleolus, and when opened was found to be completely occluded by the distal thrombus. The artery was irrigated with a 2 per cent solution of sodium citrate from

FIGURE 5.

This is a photograph of the embolus and a small portion of the distal and proximal secondary thrombi attached to it removed from the popliteal artery of Case 4 seventy-two hours after the time of embolism. The central gray portion represents the embolus. The narrow part of the specimen is a portion of the distal thrombus, and its caliber indicates the extreme narrowing of the arterial tree distal to the embolus. The dark portion at the larger end of the specimen is the proximal thrombus. In contradistinction to the portion of the distal thrombus shown, it represents the entire proximal clot. Its large caliber shows how little constriction of the artery had occurred proximal to the embolus.

consist of an embolus with a distal and proximal secondary thrombus attached to it. The central, light-colored portion represented the embolus, whereas the narrow, dark-colored part was a small piece of the distal thrombus. The dark, thick portion, which was of the same

below upward, a modification of the method described by Lerman, Miller and Lund.¹² Many pieces of the distal thrombus were washed out through the opening in the popliteal artery. Even after a clear flow of the irrigating fluid had been obtained above, there was no evidence of

bleeding from the distal part of the popliteal artery, or from the posterior tibial artery. This showed that the distal secondary thrombus had extended into the branches of the popliteal artery and their tributaries to such an extent as to block all blood flow through them.

Further study of the specimen revealed the state of the arteries proximal and distal to the site of embolism. The fact that the large proximal thrombus was practically the same in diameter as the embolus itself indicates that there was little if any vasoconstriction of this portion of the popliteal artery. In addition, it is to be emphasized that this thrombus was relatively short, so that it interfered very little with collateral circulation, by occluding the openings of arterial branches arising from the popliteal artery above the embolus. In contradistinction, the secondary thrombus distal to the embolus was extremely small in diameter. This indicated the extreme degree of vasoconstriction present in the arteries distal to the site of embolism. Exploration of the posterior tibial artery at the ankle showed that this vasoconstriction and thrombosis extended distally into the foot.

An analysis of the following case, which was treated by the intermittent negative-positive-pressure (pavex) method, gives further evidence of the importance of early treatment in preventing secondary thrombus formation.

CASE 5. A 36-year-old woman was admitted to the hospital because of rheumatic heart disease with mitral stenosis. Five days after admission she first noted numbness of the left foot. An hour and a half later, the left leg was cold and cyanotic up to the knee. There was complete loss of sensation over the entire foot, and the patient could not move the foot or toes. No pulsations were palpable in any of the vessels of both legs, including the femoral arteries. The blood pressure and pulsations were normal in the arm vessels. A diagnosis of a so-called "rider" embolus at the bifurcation of the aorta was made. The left leg remained cadaveric in appearance, but the right maintained a normal appearance, with complete muscular control. The left leg was placed in the negative-positive-pressure apparatus $3\frac{1}{2}$ hours after the initial symptoms were noted by the patient. Ten cubic centimeters of 1 per cent novocain was injected in the neighborhood of the 2nd, 3rd and 4th lumbar vertebrae on the left side. This was done to produce temporary peripheral vasodilatation by interrupting the sympathetic vasoconstrictor pathways, so that an active collateral circulation might be developed. The negative-positive-pressure treatments were continued on the left leg for about 48 hours and then for decreasing intervals, until they were stopped on the 8th day. The right leg was also given some treatment because its circulation began to fail. It responded more rapidly than the left, indicating a better collateral blood supply. The treatments to the right leg were continuous for the first 24 hours, after which they were given at intervals and gradually diminished until they were also stopped on the 8th day after the embolism occurred. At that time, both legs had normal color and warmth, and there was complete control of all the muscles. There was no evidence of gangrene. Yet examination revealed no pulsations in any of the arteries of either leg. Three days later, the patient suddenly lost consciousness and developed a hemiplegia. Death followed in 12 hours. At the post-mortem examination the cause of death was found to be an embolism of the basilar artery and the right postero-medial ganglionic artery.

It is true that this patient survived the primary embolism for only eleven days, which according to some writers is too short a time to allow restoration of circulation in an affected limb. However, it is to be noted that the return of the circulation in the legs was so complete that treatments in the pavex apparatus were discontinued 3 days before death. It seems unquestionable that if this patient had not developed embolism of the cerebral arteries, the circulation of the legs would have been re-

FIGURE 6.

This is a diagrammatic sketch to show the location of the emboli and thrombi in the aorta and its main tributaries in Case 5. On the right this clot extended down to the point where the deep epigastric artery arises from the external iliac. On the left the secondary thrombus had occluded the left common femoral artery. It is to be noted that the vessels distal to the emboli and thrombi remained patent and contained no blood clot.

stored for an indefinite period. An analysis of the post-mortem findings substantiated this view.

At the autopsy it was found that the aorta was occluded at its bifurcation by an embolus and that there were thrombi extending from this distally into the right and left external and internal iliac arteries. On the right, the thrombus extended 6 cm. down the external iliac artery and about 1 cm. above the profunda femoris. In the right internal iliac artery it extended a distance of 9 cm. On the left, the thrombus in the external iliac artery was 17 cm. in length and occluded the bifurcation of the common femoral artery. It was thought that the most distal part of this thrombus at the origin of the profunda represented an embolus, probably a portion of the aortic one, which had broken off and lodged in the femoral artery. The location of the emboli and the thrombi are shown diagrammatically in Figure 6.

The chief significance of these findings was that despite the fact that the embolism occurred ten days previously, the secondary thrombus formation distal to the emboli was checked by the treatment administered. The initial vasoconstriction in the arteries distal to the site of embolism was counteracted for several hours by paravertebral novocain injection about the lumbar sympathetic ganglia. During this time and subsequently, an active circulation of blood through these vessels was enhanced by the use of the negative-positive-pressure apparatus.

The post-mortem findings indicated that this type of treatment, if administered early, aids the development of the collateral circulation around the site of embolism. In addition, by maintaining a blood flow of sufficient volume and rapidity, intra-arterial clotting distal to an embolus does not take place to a sufficient degree to jeopardize the life of the affected limb. It is probable that secondary thrombosis distal to the embolus may occur, but that it is limited to a segment of the arterial tree in which there is apt to be stagnation of the blood. Thus, it will be found to be present between the embolus and the point where the blood re-enters the main arterial channel through collateral blood vessels. This point is especially well illustrated in this case in the right extremity in which the secondary thrombus extended distally to just above the origin of the deep epigastric artery, through which, presumably, blood entered the femoral artery by way of the arteries of the anterior abdominal wall. From an examination of the specimen it should also be noted that no thrombus was found proximal to the embolus at the bifurcation of the aorta.

CONCLUSIONS

From the analysis of these cases of peripheral embolism in which the postembolic findings are considered typical, the following generalizations may be made.

Marked peripheral vasoconstriction of the arteries distal to the site of an embolism uniformly occurs very soon after the lodgment of the embolus. In one case it was noted within an hour and a half. The artery proximal to the embolus, on the other hand, is not affected to the same degree: it maintains its normal caliber except for a very short zone of constriction adjacent to the embolus. The peripheral vasoconstriction plays an important role in the formation of the secondary distal thrombus, which nearly always forms

after the lodgment of the embolus, if early adequate treatment is not instituted.

A thrombus may form distal to an embolus as early as nine hours after the occurrence of the embolism. By then it may be so extensive as to prevent the return of the circulation to the extremity, even though the embolus and a considerable portion of the thrombus are removed.

Thrombus formation proximal to the embolus does not form so extensively as that distal to the embolus. Even after seventy hours in one case, it was only 3 cm. long. It can readily be removed. It is less likely than the distal thrombus to interfere with the collateral circulation, because usually it extends only up to but does not occlude the first major arterial branch proximal to the embolus.

The presence of a distal thrombus virtually precludes the return of circulation to the extremity, because it is impossible, even if the main artery is cleared of blood clot, to remove the thrombus from the smaller tributaries of the peripheral arteries.

Failures in the treatment of peripheral embolism can in most cases be directly attributed to the formation of a secondary thrombus distal to the embolus.

Restoration of the circulation following peripheral embolism can be brought about by means of early (within six hours) adequate treatment, such as embolectomy or the use of intermittent venous congestion therapy, and the interruption of the sympathetic pathways by novocain or alcohol paravertebral lumbar injection. In conjunction with these forms of treatment, the intravenous use of heparin should prove of value in preventing the distal secondary arterial thrombosis.

THE COMPARATIVE PROTHROMBIN RESPONSES TO VITAMIN K AND SEVERAL OF ITS SUBSTITUTES IN A CASE OF NONTROPICAL SPRUE*

J. GARROTT ALLEN, M.D.†

CHICAGO

RECENTLY Butt, Snell and Osterberg¹ and Engel² have found that prothrombin deficiency may appear in nontropical sprue. The reduction of plasma prothrombin in sprue presumably represents a general impairment in the absorption and utilization of fats and fat soluble substances, including the fat soluble vitamin K. It is the purpose of this report to present a case of nontropical sprue that developed a severe hemorrhagic tendency, which was completely relieved by the administration of vitamin K or some of its substitutes. This case is of interest in that the intermittent use over an eight month period of several substances possessing vitamin K activity afforded an opportunity to compare the relative antemorrhagic values of these substances in the same patient.

This case was presented in detail elsewhere by Childs and Dick³ before these prothrombin studies were made. The early history is referred to only briefly in this report.

CASE REPORT

A 31 year-old white, married woman was admitted to the Billings Hospital, October 29, 1937, on the medical service of Dr. George F. Dick. During the 3 years preceding admission she experienced marked loss of appetite, increasing weakness, glossitis and voluminous pale tan stools, foul in odor and occurring typically during the morning hours. The weight gradually fell from 126 to 92 pounds during this period.

On admission to the hospital the patient was found to have a macrocytic anemia that responded slowly to iron and liver extracts. Ecchymotic subcutaneous areas were present over the body and extremities, these were not affected by the administration of synthetic vitamin C until the general condition improved several weeks later. Pancreatic juice, obtained from dogs with bile fistulas, was provided by Dr. Lester R. Dragstedt of the Department of Surgery of the University of Chicago, it seemed to exert a definite therapeutic effect on the stool weight, its fat content and the frequency of bowel movements. Stool cultures were negative for monilia after incubation for 11 days. Fat tolerance tests yielded a flat curve whether the test material was given in water or in pancreatic juice.

X-ray evidence of edema of the jejunum, terminal ileum and colon was found.

The patient was discharged March 4, 1938, improved, but was readmitted 3 weeks later complaining of sensations of numbness and tingling in the hands and feet, associated

with some recent weight loss. A moderate anemia was again present, and a blood calcium of 6.2 mg per 100 cc. was found. The patient was given a course of liver extract and daily oral doses of 30 gm of calcium gluconate, 0.2 gm of ferrous sulfate, 40 gm of Armour's pancreatin, 3 ABD capsules, 36 gm of brewer's yeast and 0.075 gm of synthetic vitamin C. Improvement was rapid and she was discharged 1 month later, continuing the above mentioned medications and a diet containing 150 gm of carbohydrate, 85 gm of protein and 140 gm of fat. The course on this regime at home was satisfactory until January, 1939, when the taking of liver extract and pancreatic substance was discontinued for a few days. By February 8 the glossitis had returned, the patient was having frequent bouts of epistaxis, and stools were being passed three or four times daily.

The patient was readmitted on February 16, and a regime similar to the previous hospitalization was instituted. Improvement was slow, and she was discharged again on May 20 on a diet containing 200 gm carbohydrate, 175 gm protein and 90 gm fat. At home she continued to take the same medicinal agents with the daily addition of 20 drops of Drisdol and 0.001 gm of nicotinic acid, on weekly visits to the clinic she was given 3 cc. of Lederle's liver extract concentrate intramuscularly, and 0.05 gm of thiamin chloride intravenously.

The general condition on this regime was satisfactory except for the reappearance of bleeding gums and ecchymosis in July. This hemorrhagic tendency increased, and the menstrual flow in August was extended to 11 days instead of the normal 3 or 4. On September 6, the patient was once more readmitted in an effort to control the bleeding. The prothrombin concentration was 15 per cent of normal, as determined by a modified one-stage technique.⁴ Alfalfa concentrate (Abbott)⁵ was then given in doses of 2 cc four times daily. The prothrombin elevation was sluggish, but after 4 days a level of 38 per cent was reached, after which no bleeding occurred. A prothrombin value equivalent to the normal control (100 per cent) was obtained by the 17th day. The alfalfa concentrate was then discontinued and the patient was discharged on September 25. The prothrombin level was periodically checked and by November 7 had fallen to 33 per cent of normal, at which time several ecchymotic areas appeared. Alfalfa concentrate was again given in similar dosage for 14 days before a normal prothrombin value was reestablished. On November 21, the dose of concentrate was reduced to 2 cc daily for a 2 week period, but on this quantity the prothrombin level slowly fell. The concentrate was then discontinued, and weekly prothrombin determinations were made until February 7, 1940, when the patient again exhibited numerous ecchymoses and bleeding gums. A vitamin K substitute, 2-methyl 1,4 naphthoquinone (Lilly), administered orally in doses of 2 mg four times a day without bile salts, produced a normal prothrombin level in 13 days, this substance was then discontinued. By March 31 the prothrombin level had fallen to 43 per cent of normal. This deficiency was treated by giving a sulfonated derivative of the 2-methyl 1,4 naphthoquinone by vein in doses equivalent

*From the Department of Surgery, University of Chicago.

†This work was aided by a grant from the Douglas Smith Foundation for Medical Research, University of Chicago.

†Douglas Smith Fellow, University of Chicago, Class of 1937.

alent to 12 mg. of the latter once daily on March 21, 23 and 25. By March 27 the prothrombin value was normal.

No further vitamin K therapy was given until April 13, when a prothrombin concentration of 60 per cent was found. At this time 2-methyl-3-phytyl-1,4-naphthoquinone (Merck), identified as synthetic vitamin K₁,⁶ was administered in peanut oil in doses of 2 mg. four times daily without bile salts. In spite of the uninterrupted use of this substance the prothrombin continued to fall slowly over a 12-day period. By April 25, when it had reached 38 per cent, this substance was discontinued, and the 2-methyl-1,4-naphthoquinone derivative was again employed in daily oral doses of 8 mg. The prothrombin

It is generally agreed that in sprue the excessive excretion of fat is due to poor absorption, but it is possible that other factors may be involved.⁹ The malabsorption of fat in this disease presumably could give rise to prothrombin deficiency by diminishing the absorption of fat-soluble vitamin K. However, the slow response of prothrombin to both the oral and parenteral administration of the vitamin and its substitutes in the case reported here suggests that the prothrombin deficiency was due to impairment of the hepatic elaboration of

FIGURE 1. Prothrombin Responses to Vitamin K and Three of Its Substitutes.

level again began to rise, reaching normal after fourteen days, a response quite comparable to the earlier course with this substance.

DISCUSSION

It is now well established that the absorption of fat-soluble vitamin K is essential for the elaboration of prothrombin by the liver.⁷ Thus any defective absorption of the vitamin or any impairment of the production of prothrombin by the liver may lead to prothrombin deficiency. The lowered prothrombin in cases of obstructive jaundice is due primarily to impaired absorption of fat-soluble vitamin K. The prothrombin response to this vitamin in obstructive jaundice is exceedingly rapid once the absorption defect has been corrected by the administration of bile salts. In patients whose prothrombin deficiency results from cirrhosis the response to the vitamin is sluggish or entirely lacking.⁸

prothrombin as well as to poor absorption of the vitamin. No other evidence of liver insufficiency was found.

The antihemorrhagic therapy included the following courses: alfalfa concentrate (natural vitamin K₁), two courses; 2-methyl-1,4-naphthoquinone, two courses; an aqueous soluble sulfonated 2-methyl-1,4-naphthoquinone, one course (given parenterally); and 2-methyl-3-phytyl-1,4-naphthoquinone (synthetic vitamin K₁), one course. The prothrombin response to each of these substances is graphically illustrated in Figure 1. In considering the antihemorrhagic values of these various substances, Fernholz and Ansbacher¹⁰ have recently stated that the potencies of the naturally occurring and the synthetic (2-methyl-3-phytyl-1,4-naphthoquinone) vitamin K₁ are essentially equivalent when compared in doses of equal weight; the 2-methyl-1,4-naphthoquinone is approximately four times as potent as either of these

substances. One cubic centimeter of the alfalfa concentrate employed in this study is said to contain a quantity of natural vitamin K₁ equivalent in activity to 1 mg. of 2-methyl-1, 4-naphthoquinone.⁶

When 8 cc. of the alfalfa concentrate or 8 mg. of the 2-methyl-1, 4-naphthoquinone was given in this case, the prothrombin responses, as expected, were quite similar. However, when 8 mg. of the synthetic vitamin K₁ was administered, the prothrombin actually fell from its pretherapeutic level of 60 per cent to 38 per cent over a thirteen-day trial period. The failure of this substance to elevate the prothrombin was undoubtedly due to the low dose, which obviously was only equivalent to 2 mg. of 2-methyl-1, 4-naphthoquinone. At the end of this test period an 8-mg. daily dose of 2-methyl-1, 4-naphthoquinone was substituted for the synthetic vitamin, and in response to this substance the prothrombin rose to normal over a fourteen-day period. A maintenance dose of 2 cc. of the alfalfa concentrate, a quantity equivalent to 8 mg. of the synthetic vitamin K₁, was also ineffective in preventing a decline in the prothrombin level. The activity of the sulfonated compound given intra-

venously cannot be compared with the potencies of the compounds that were administered orally.

CONCLUSION

It can be concluded from the studies on this patient that natural (alfalfa concentrate) and synthetic (2-methyl-3-phytyl-1, 4-naphthoquinone) vitamin K₁ were considerably less active than the 2-methyl-1, 4-naphthoquinone.

THE SYMPTOMATIC TREATMENT OF FUNCTIONAL DYSMENORRHEA BY AMPHETAMINE (BENZEDRINE) SULFATE*

Z. EILEEN TAYLOR, M.D.†

WINCHESTER, MASSACHUSETTS

IN A practice including a high percentage of young women patients, the problem of the treatment and management of dysmenorrhea becomes extremely important. In some cases painful menstruation is a sign of underlying organic disease or hormone dysfunction. However, there remain a certain number of sufferers from dysmenorrhea in whom careful gynecologic examination and laboratory investigation reveal no such cause. The pain is often so severe that bed-rest during part of each menstrual period becomes necessary. In such cases the efficiency of the patient is markedly reduced, not only by pain but also by the marked depression that is usually a factor. This psychologic component of dysmenorrhea is also usually found in cases in which abnormal conditions are present in the uterus or in its nerve supply. Although the pain can to some

extent be controlled by salicylates or codeine, the treatment by such methods has not been entirely satisfactory in controlling the depression, fatigue and inertia.

It was thought possible that a therapeutic agent causing relaxation of smooth muscle in general, and at the same time an increase of the sense of well-being, might be of value in the treatment of functional dysmenorrhea. For this reason amphetamine (Benzedrine) sulfate was tried.

Halpern¹ showed that amphetamine sulfate could be considered a physiologic antagonist of such spasmogenic drugs as acetylcholine and pilocarpine when acting on the uterus of the rabbit. Boyd,² on the other hand, presented evidence that on isolated uterine muscle of the rabbit, amphetamine sulfate produced increasing contraction. Hundley et al.³ found that the drug contracted uterine muscle strips in the guinea pig but relaxed them in the rabbit, and that whether it was injected

*From the Medical Services, New England Hospital for Women and Children.

†Visiting physician, New England Hospital for Women and Children.

into living persons or applied to surviving human uterine muscle strips, the predominant effect was an increase of uterine tone and a diminution of the amplitude of contractions.

Bakacs,⁴ who treated climacteric symptoms with amphetamine sulfate, reported improvement of menstrual disorders in certain cases. Hundley et al.³ had good results administering 10 to 20 mg. amphetamine sulfate to relieve attacks of primary dysmenorrhea in a series of 91 working girls.

Since amphetamine sulfate has been successfully used for dysmenorrhea in the author's practice for three years, it seemed interesting to publish the records of 4 typical cases that were thoroughly studied and controlled. The cases were chosen from a series of 34, and were the most serious seen during the three-year period of observation.

METHOD

A complete medical history was obtained and a physical examination made in each case, and 3 patients were referred to consulting gynecologists. In no case was any underlying gynecologic disorder responsible for the dysmenorrhea. Glandular dysfunction and organic lesions, when present, were treated appropriately before beginning treatment with amphetamine sulfate.

The patients were given three trial doses of 2.5, 5.0 and 10.0 mg. amphetamine sulfate during intermenstrual periods, and were observed for an hour in order to determine whether or not any sensitivity to the drug or untoward reactions would occur. A sufficient quantity of the drug for the next menstrual period was then given, without comment on the nature of the medication. The patients were instructed to take 10 mg. (one tablet) of amphetamine sulfate before breakfast for two days before the expected period and including the day of the period, and to repeat the dose if the pain was not relieved. They were not permitted to take more than 20 mg. a day, or to take the second tablet after 2 p. m., without advice from the physician. The treatment lasted three or four days, depending on the expected duration of symptoms. On alternate periods the patients were given placebos or analgesics (salicylates or codeine), but they did not know what medication they were receiving. No leading questions were asked, but the patients were asked to describe the symptoms at each menstrual period. The various findings were later correlated.

CASE REPORTS

CASE 1. A 27-year-old patient stated that her periods began at the age of 12 and recurred regularly every 28 days, lasting 2 or 3 days and requiring one or two pads a day. From the onset there were symptoms of dysmenorrhea,

with marked aggravation since 1926, the year before her marriage. The dysmenorrhea usually started 1 week before the period, confined the patient to bed until the flow had ceased and was characterized by severe low abdominal and back pain, bearing-down in nature but without radiation and without leukorrhea or intermenstrual bleeding. The condition was complicated by an anxiety depression, with financial worries, which resulted in maladjustment.

The patient was married in 1927. In May, 1931, a normal-sized baby was delivered by cesarean section, necessitated by the presence of a small pelvis. Pregnancy had been difficult.

In June, 1935, the patient complained of constant pressure and a heavy feeling in the pelvis, for which she was treated by douches and tamponage. The next two periods were unusually profuse, suggesting the possibility of endometriosis, but this was not found by the gynecologist to whom she was referred.

Examination in January, 1936, revealed a marked hypochromic anemia and hyperthyroidism, with a basal metabolic rate of +39 per cent. Thyroidectomy was performed in March, after which the basal metabolic rate fell to normal and the symptoms of hyperthyroidism disappeared. The anemia was successfully treated with ferrous sulfate.

The dysmenorrhea was not in any way relieved by pregnancy or by thyroidectomy, and menstrual pain was the chief complaint. The patient was referred for complete gynecologic examination, but no positive findings were obtained. Administration of 2000 international units of Theelin daily for five months, beginning in January, 1937, caused no improvement. Analgesics were also ineffective, and the patient became more depressed with each period.

Amphetamine sulfate therapy was begun in December, 1937. A dose of 10 mg. gave marked relief of pain and a general increase in the sense of well-being, but it was found that repetition of the dose 3 hours later gave even better results. The patient remained in bed for 2 or 3 hours after taking the drug, and was then able to get up and to carry on her work, both as a housewife and as a saleswoman. The medication has been uniformly successful for 2 years. The substitution of placebos or salicylates always resulted in a return of the original symptoms of pain, depression and incapacity.

CASE 2. A 16-year-old single girl reported that menstruation started at the age of 14 with a normal amount of flow, usually lasting 3 or 4 days. Dysmenorrhea began at the onset of each period, with lumbar and low abdominal pain that was bearing-down and cramplike in character and radiated down both legs. Each attack was associated with nausea and vomiting, chills and a clammy skin with marked pallor. The patient had what appeared to be a marked vasomotor reaction with each period and was always confined to bed during the 1st day.

Physical examination and history were essentially negative, aside from a slightly masculine distribution of hair and the complaint of dysmenorrhea. In view of a basal metabolic rate of -10 per cent, the patient was given 2 gr. of thyroid daily for a period of 4 months. This therapy diminished the nausea and vomiting and also relieved the cramps to a certain extent, but the relief was not sufficient to enable her to be up during the 1st day of her period.

Thyroid was discontinued in September, 1938. Ten milligrams of amphetamine sulfate was given daily from the expected onset of menstruation until the morning of the 2nd day of the period. There was almost complete relief from all symptoms, except when menstruation started before the amphetamine sulfate was given, but at such times the drug brought complete relief. The nausea and

vomiting and the peculiar skin sensations were completely abolished, and the patient was able to go to school without interruption. When placebos, salicylates or codeine were substituted, all the symptoms returned. The medication has continued for a year, with no signs of tolerance. Thyroid was later added to the treatment because of evidence of mild hypothyroidism. During the last two months the patient has received a combination of thyroid and amphetamine sulfate, beginning one week before the expected period, with excellent results.

CASE 3. The menstruation of a 32-year-old married woman began at the age of 11 and recurred every 30 days with a normal amount of flow. Dysmenorrhea, characterized by severe low abdominal pain, appeared at the onset of the menses, and necessitated bed rest the first half-day of the period. When dysmenorrhea did not occur there was an attack of migraine for 2 days previous to the onset of menstruation. During all periods the patient felt uncomfortable and markedly depressed and fatigued. Pregnancy 3 years before the first visit had brought no relief of the dysmenorrhea, although codeine alleviated the pain to some extent.

Physical and gynecologic examinations were essentially negative, except for the presence of a small fibroid.

Amphetamine sulfate was found to give relief from pain and depression, beginning a half-hour after ingestion and becoming complete in 2 hours. Five to 7.5 mg. were sufficient in this case, whereas 15 mg. or more occasionally produced tachycardia which lasted for 30 minutes. Substitution of placebos resulted in the return of the symptoms.

CASE 4. The onset of the menses in a 17-year-old girl was at 14 years, and they recurred at intervals of 4 to 5 weeks thereafter. The amount and duration of the flow were normal. There was dysmenorrhea from the beginning, occurring 2 or 3 days prior to the period, with generalized aching and low abdominal pain and with nausea and vomiting on the 1st day of the flow. The pain lasted about 2 days, but usually recurred on the 5th or 6th day. There was no constipation, but usually a looseness of the bowel movements. Soreness of the breasts was present just before the period. The pain and depression obliged the patient to remain away from school during attacks.

Physical and gynecologic examinations were essentially negative except for the presence of a femoral hernia, which gave little difficulty.

A daily dose of 5 mg. of amphetamine sulfate was sufficient to control all symptoms in this patient, enabling her to attend school without interruption for 6 months, except when incapacity resulted from the substitution of placebos.

The observations included a group of 30 additional patients. Of these, 20 were studied for a period of four months or more. In 4 cases dysmenorrhea did not occur while under medication, and 7 patients reported complete relief of symptoms within 2 hours of taking the drug. Twelve patients reported marked relief of symptoms and an increased sense of well-being, and 5 reported that the relief was not sustained; 2 believed that their symptoms were, if anything, worse.

In the total group of 34 patients there were only two untoward reactions. The first was a manic phase induced by a test dose of 5 mg. of the drug in a patient who later was proved to have a manic

depressive psychosis. The second was in a patient with anxiety neurosis who refused medication because palpitation occurred with the test dose. In the entire series there was no indication of tolerance or habit formation. No patients expressed a desire for the drug in intermenstrual periods.

Amphetamine sulfate was not observed to have any effect on the amount of menstrual flow.

DISCUSSION

Amphetamine sulfate is not suggested as a remedial measure for dysmenorrhea in the presence of underlying pathologic conditions. Prior to any symptomatic treatment, competent gynecologic examination should of course be made, and indicated measures taken; when a positive diagnosis of endocrine dysfunction is made, appropriate therapy should be undertaken. But it is significant that the symptoms of dysmenorrhea often fail to yield to such treatment. An example is seen in Case 1. This patient was generally benefited by thyroidectomy and Theelin medication, but the dysmenorrhea was not relieved. The symptomatic improvement must be attributed to one or more of the various effects of the drug, that is, improvement of mood, relief from fatigue and relaxation of smooth muscle. The implication is that cases of essential dysmenorrhea have too frequently been ascribed to some unspecified endocrine imbalance, whereas endocrine disorders and essential dysmenorrhea should be treated independently.

It is impossible to determine what part was played by the relief of spasm and pain through the relaxation of smooth muscle, but it seems probable that the disappearance and prevention of abdominal pain may be partly attributed to this effect of the drug.

The most demonstrable value of amphetamine sulfate was in the relief of depression and fatigue. This effect may in turn have favorably influenced other symptoms, such as nausea, which are often psychogenic. That this effect was real, and not imaginary, is proved by the fact that substitution of placebos never failed to cause a recurrence of the symptoms.

Objections to this treatment in ambulatory patients are based on the possibility of reactions, tolerance and habit formation. Reactions were forestalled by test doses, and in the rare cases in which they occurred subsequently, could be controlled by reducing the dose. Tolerance was not developed, nor could it be expected under spaced medication of this type: the dosage never had to be increased during the three years of the experiment. Medication was never requested during intermenstrual periods; the patients in whom fa-

avorable responses were obtained wanted the drug for its specific effect in relieving their symptoms, but never seemed desirous of obtaining the euphoric effect when it was not recommended for their condition.

SUMMARY AND CONCLUSIONS

Amphetamine (Benzedrine) sulfate, in doses of 5 to 20 mg. a day, was used in the treatment of 34 cases of essential dysmenorrhea. Four of these were studied in detail. It was found that the drug relieved pain, fatigue and depression in cases in which other measures had failed. This finding was confirmed by the substitution of placebos or other medication during alternate periods. The rationale of the therapy is discussed.

In the 30 additional cases, 40 per cent obtained complete relief and an equal number moderate relief. In 16 per cent the apparent benefit of the drug was not maintained, and in 2 cases (6 per cent) the patients reported that they were worse under medication.

It is concluded that amphetamine sulfate is a valuable drug for the treatment of dysmenorrhea and that it is well adapted to ambulatory patients.

MEDICAL PROGRESS

MEDICAL ASPECTS OF OBSTETRICS

THOMAS R. GOETHALS, M.D.*

BOSTON

DURING the last twelve months various contributions to the literature dealing with the medical phases of obstetrics have appeared. As usual, the knowledge of such progress as has been made must be gleaned from observations and opinions, which at times confirm and at other times refute observations previously made and opinions previously expressed.

The toxemias of pregnancy have claimed their usual share of attention, with a continuing contest between etymologists and etiologists concerning a proper system of nomenclature. The latter school of thought contend that the very existence of so-called "toxemia of pregnancy" is doubtful. Peters et al.^{1,2} state that toxemic pictures may resemble all the disorders that outside of pregnancy give rise to arteriolar disease, hypertension and functional impairment of the kidneys. Pyelitis, in their opinion, plays an important part because the physiologic hydronephrosis of pregnancy renders infection particularly malignant. According to them, women who have pyelitis when pregnant seldom escape irreparable and enduring damage if the pregnancy is allowed to continue. In support of this belief they report finding among 93 women with pyelitis as a complication of pregnancy 25 cases of hypertension or edema or both before pregnancy was terminated. Weiss and Parker³

conclude that chronic pyelonephritis results in the gradual diminution of kidney structure and in decreased renal function, and state that patients who have had pyelonephritis in early childhood show a marked tendency to develop a certain type of toxemia.

The role of renal damage from a pre-existing pyelitis or pyelonephritis in the etiology of the toxemic syndrome is discussed by Crabtree and Reid.⁴ These authors consider that early interruption of pregnancy because of the occurrence of pyelitis or pyelonephritis, as advocated by Peters, requires further investigation before being accepted. They report a series of 45 cases of pregnancy pyelonephritis in which the infection had occurred from five to ten years before the investigation was undertaken. In their conclusions they state that data have not yet been produced to indicate to what extent pyelonephritis of pregnancy shortens life; though in many cases it is a progressive disease, and though a high percentage of patients suffer appreciable damage to their kidneys, which is demonstrable from five to ten years after the infection, they believe that sufficient evidence has been produced to indicate that the aim in treatment in pyelonephritis associated with pregnancy should be to minimize the initial injury and clear the infection as soon as possible.

Mussey and Lovelady⁵ review the relations of urinary infection to toxemia, comparing a series of 117 proved cases of pyelitis complicating preg-

*Assistant professor of obstetrics, Harvard Medical School, assistant obstetrician, Boston Lying-in Hospital, obstetrician, Massachusetts General Hospital.

nancy with a series of 163 cases of acute hypertensive toxemia of late pregnancy. Ninety-two patients in the former group showed pyelitis during pregnancy, 25 in the puerperium. In 3 patients, pyelitis of pregnancy was followed or accompanied by the development of acute toxemia. One patient with fulminating pyelonephritis died of acute renal failure probably associated with cortical abscesses, permission for necropsy was not obtained, and it is debatable whether or not this case should be classed as a true pre eclamptic toxemia. None of the 163 patients in the toxemic group gave a history of pyelitis prior to the first pregnancy, 10 of 6 cases pyelitis developed during the puerperium. The authors conclude that acute pyelitis of pregnancy when treated promptly is not prone to cause pre eclamptic toxemia, and that following one attack of acute pyelitis of pregnancy the majority of such women do not exhibit symptoms of residual renal damage.

Such studies as those quoted in the two preceding paragraphs are in no sense contradictory to the findings of Peters and of Weiss and Parker that renal damage found at autopsy may frequently be traceable to a previous severe or long standing infection. In fact they show, by clinical observation, that functional damage to the renal and vascular systems occurs following a certain proportion of cases of pyelitis and pyelonephritis. To date, however, they have not proved that these conditions are certain to cause renal damage within the space of the childbearing period of life, or that the occurrence of pyelitis or pyelonephritis in pregnancy is per se an indication that interruption of the pregnancy is indicated as the cardinal treatment to be employed.

Tenney and Parker⁶ take issue with the usually accepted belief that hypertension, edema and albuminuria occurring in a pregnant woman necessarily justify a diagnosis of toxemia. They maintain that true toxemia, whether or not there is underlying or pre existing hypertension or renal disease, can be accurately judged by certain changes in the placenta, which they describe as widespread hyaline syncytial degeneration associated with marked villous congestion. This claim leaves the clinician in a dilemma when he is confronted with a pregnant woman presenting the aforesaid triad of hypertension, edema and albuminuria. Since, according to this concept, the means of diagnosing true toxemia—to wit, the placenta—is unavailable until after the uterus has been emptied by natural or induced means, the primary diagnosis seems to be narrowed down to a choice between hypertensive disease and renal disease, neither of which can be proved without

prolonged study and observation, unless one is to postulate the existence of false as well as true types of toxemia. Further discussion along this line, however, might become Gilbertian, since the term "toxemia" still eludes concrete definition, useful though it may be as the name of a syndrome.

Despite controversy as to etiology, the etymologists have not been entirely inactive. Wellen⁷ discusses a workable classification for the so-called "toxemias of pregnancy" that differs only in slight detail from the classification agreed on by a subcommittee of the American Committee on Maternal Health. The latter includes the following headings: vomiting of pregnancy, acute yellow atrophy of liver, eclampsia, severe pre eclampsia, mild pre eclampsia, hypertensive disease, and renal disease. To this classification Stander,⁸ previously a formulator of the Johns Hopkins classification, which was partially discussed in this review⁹ in 1939, has given approval, correlating his original concept of low reserve kidney with mild pre eclampsia and hypertensive disease, and his original grouping of chronic nephritis with hypertensive disease and renal disease.

Reid and Teel¹⁰ have contributed an article dealing with cardiac asthma and acute pulmonary edema complicating the toxemias of pregnancy, complementary to an article on the same subject published by the same authors and Hertig¹¹ in 1937. They find that both toxemic patients with previously normal vascular and renal systems and those with antecedent hypertension may have paroxysmal attacks of cardiac asthma with acute pulmonary edema; they attribute these conditions to sudden left-ventricular failure. Therapy consists in large doses of morphine with venesection, or in peripheral venostasis when indicated by severe pulmonary edema, followed by rapid digitalization and dehydration, and delivery within a few days after the attack has been controlled. The authors also believe that the distressing pulmonary edema often encountered in severe and fatal eclampsia is a result of acute left-ventricular failure; for this reason rapid and full digitalization of all eclamptic patients is indicated.

For the treatment of eclampsia, veratrum viride has been reintroduced, this time from the Ohio Valley. In 1935 Bryant,¹² of Cincinnati, reported a series of 121 consecutive cases treated with this drug, with 12 deaths, a mortality of 10 per cent. During the last year Bryant and Fleming¹³ have published a new series of 120 cases thus treated, 54 of which had been included in the 1935 paper, two deaths occurred, a mortality of 2 per cent. In addition to veratrum viride, however, which serves as a vasodilator, slowing the pulse and lowering

the blood pressure, the authors advocate the administration of 10 cc. of 50 per cent magnesium sulfate by deep injection immediately after the condition is recognized, followed by 5 cc. every six hours for four doses and by 5 cc. every twelve hours thereafter for four more doses; this drug they consider to have a dehydrating and diuretic action. In July, 1940, treatment with veratrum viride was instituted at the Boston Lying-in Hospital, with the intention of using this drug, if feasible, without the synergistic action of magnesium sulfate, according to the standard recommended by the Cincinnati investigators, *viz.*, 10 minims at once, repeating the dose every ten or fifteen minutes until the pulse rate is below 60 or the systolic blood pressure below 120; thereafter repeating in doses of 3 to 10 minims if the pulse rate exceeds 80 or the blood pressure rises above 150 systolic. To the date of publication of this report, however, insufficient evidence has accrued locally to render a judgment as to the results to be expected.

Progress in the employment of chemotherapy for puerperal and postabortal infection has been reported from various sources. Gordon and Rosenthal¹⁴ investigated 27 new cases of severe puerperal infection; 21 showed clinical response to sulfanilamide therapy, 5 gave a doubtful response and 1 gave no response. They state that sulfanilamide therapy in severe infections need not wait upon bacteriologic investigation, yet this information is of importance in deciding whether the drug should be continued in the absence of favorable clinical response. So far as these authors know, all strains of Group A streptococcus respond to sulfanilamide, but evidence in the cases of infection by anaerobic streptococci, *Streptococcus viridans*, nonhemolytic streptococci, staphylococci and colon bacilli is inconclusive.

Rosenthal and Stone¹⁵ reporting 2 cases of vegetative endocarditis due to hemolytic streptococci (Groups B and C), one postabortal and the other probably postpartal, found that massive sulfanilamide therapy failed in both cases, and that experiments in vitro and in vivo indicated the drug had little effect on these strains.

These observations bear out reports from other sources, both obstetric and nonobstetric, that sulfanilamide has its greatest value in the treatment of infections with the Group A hemolytic streptococcus. They add evidence to previous experience that bacteriologic control is necessary if the best results are to be expected from chemotherapy. Sulfanilamide may properly be used in severe infections pending bacteriologic confirmation of the identity of the organism involved, and may be

continued if culture shows the organism to be of a type against which the drug has been shown to have therapeutic value, especially the Group A streptococcus, or, despite the doubts of Gordon and Rosenthal,¹⁴ the colon bacillus. If an anaerobic streptococcus is shown to be the agent of infection, sulfanilamide is probably valueless; if the staphylococcus is found, sulfathiazole therapy promises much more favorable results.

Long et al¹⁶ have contributed a concise and informative article dealing with the toxic manifestations of sulfanilamide and its derivatives. Whereas heretofore the careful clinical and laboratory investigation of patients treated with sulfanilamide, sulfapyridine or sulfathiazole has been considered necessary, the authors are now willing to state that, with the exception of acute leukopenia, all the toxic manifestations of these drugs, which may occur in the first two weeks of therapy, can be recognized by careful clinical observation alone; therefore they believe that no physician need hesitate to administer the drugs in therapeutically adequate amounts, provided he can see his patient once a day. The requisite observations include the following:

Inquiry as to symptoms of headache or malaise, because these symptoms often precede toxic manifestations.

Examination of the scleras for jaundice, the mucous membranes for pallor and the skin for rash.

Checking of temperature to discover drug fever. If the patient complains of chills, it should be arranged to have the temperature recorded frequently.

No special precautions are required as to the urine when sulfanilamide is used. It should be measured by any household standard in all cases receiving sulfapyridine or sulfathiazole. In this way an oliguria may be detected before anuria develops. The urine should always be examined for gross blood, and the attendants should stop the drug and force fluids if oliguria develops or if the urine looks bloody.

Before instituting therapy it is important to ascertain whether the patient has taken sulfanilamide or a related drug before, and if so, whether it proved toxic. If a history of toxicity is obtained, it is best to give a small test dose (5 gr.) and to observe the patient closely before cautiously beginning chemotherapy.

This article is of considerable value in dispelling the natural uncertainty as to the advisability of chemotherapy when complete laboratory control is impossible or inexpedient. The observation of gross blood in the urine is misleading in postpartal or postabortal patients unless the specimen is obtained by catheter; hence under conditions of therapy in the home the fourth precaution mentioned by the authors above quoted may be difficult to fulfill in such cases. Fortunately, the greatest part of postpartal and postabortal sepsis is due to organisms for which sulfanilamide is indicated. The smaller group of cases in which sulfapyridine or

sulfathiazole is the agent of choice should be hospitalized, whenever possible, in the interests of better controlled observation and greater safety for the patient.

Perhaps the most publicized element of progress in the medical aspects of obstetrics during the last year has been the attention directed toward the use of vitamin K both prophylactically and therapeutically in hemorrhagic disease of the newborn.

It has long been recognized that a newborn in fact may exhibit a certain hemorrhagic tendency during the first week or two of life, which results in some cases in death from rapid exsanguination. Bleeding may occur from the umbilical cord, from the gastrointestinal tract, beneath the skin, from the urinary tract or into the cerebrospinal system. This syndrome, recognized clinically as hemorrhagic disease of the newborn, is separate and distinct in etiology from the hemophilic and purpuric types of diathesis, and its occurrence is limited predominantly to the first week, and practically always to the first two weeks of neonatal life. The only reasonably effective method of therapy known to date has been prompt transfusion with whole blood.

Evidence is rapidly accumulating that the blood of newborn infants shows a low level of prothrombin. Kato and Poncher¹⁷ give a historical résumé of prothrombin determinations, referring to the previous publications of Quick and Grossman,¹⁸ Brinkhous, Smith and Warner¹⁹ and others, which had demonstrated low prothrombin levels in the blood of newborn babies. Kato and Poncher report the prothrombin clotting time, by a micromethod that they describe, of 173 newborn infants, both mature and immature. In 100 mature infants the average time was 43.2 seconds on the first day of life, gradually shortening to 25.0 seconds by the tenth day. In 73 premature infants the average figure of 46.5 seconds was found on the first day.

Waddell and Lawson²⁰ have investigated 191 newborn infants, showing that the period of most marked prothrombin deficiency occurred at the ages of forty-eight and seventy-two hours. This is in accord with the common obstetric experience that the bleeding tendency in otherwise normal newborn infants is apt to manifest itself on the second or third day after delivery.

Rush²¹ compared the fibrinogen and prothrombin levels of samples of maternal and umbilical cord blood taken at the time of delivery of 18 patients with the values found in 6 normal persons. The fibrinogen level of cord blood was found to be normal, but the prothrombin content was reduced. Both the fibrinogen and pro-

thrombin contents of maternal blood at the time of delivery were found to be above normal. The conclusion reached was that the prolonged prothrombin clotting time of cord blood is not due to a deficiency of plasma fibrinogen. In a later article the same author, in collaboration with Norris,²² substantiates his previous findings concerning the respective prothrombin contents of maternal and cord blood.

Enough of the available evidence has been quoted in the preceding paragraphs to indicate the chemical background for the tendency of newborn infants to bleed. Hemorrhagic disease is thus seen to be a deficiency disease. If an antidote is available to make good the deficiency, its administration should prevent the condition from developing and should have therapeutic value against its manifestations if perchance it should develop. The evidence secured to date suggests that vitamin K is such an antidote.

Cheney²³ states that hemorrhagic disease of the newborn is one of two classes of disorders definitely associated with vitamin K deficiency that are benefited by vitamin K therapy. Waddell and Lawson,²⁰ reporting the findings in 181 infants treated with 0.5 cc. of natural vitamin K concentrate, or its equivalent in 2 methyl 1,4 naphthoquinone, immediately after birth and at the end of twenty-four and forty-eight hours, and comparing them with those obtained in 191 control infants, conclude that such a regime will give adequate protection against the physiologic prothrombin deficiency characteristic of newborn life. Fitzgerald and Webster²⁴ report a study to determine the effect of vitamin K administered to women in labor. Fifty patients treated with oral Klotogen showed a definite rise in their prothrombin levels at the end of labor; there was also a definite rise in the average level of prothrombin in the cord blood. The same findings were obtained in 19 patients to whom the authors administered synthetic Vitamin K intravenously. A series of 20 cases in which sodium pentobarbital was given as an analgesic showed a definite depression of the prothrombin levels of both mothers and infants.

Hellman, Shettles and Eastman,²⁵ publishing a review of one year's experience with vitamin K in obstetrics, state that the plasma prothrombin level of the newborn infant can be raised severalfold by administering vitamin K to the mother antenatally, even when it is given as late as four hours before delivery; and that although the feeding of vitamin K to the baby after birth also increases its prothrombin concentration, the levels reached are not so high as those achieved by antenatal ad-

ministration to the mother. Comparing a series of 384 cases in which each mother was given 2 mg. of 2-methyl-1,4-naphthoquinone orally during labor with a control series not so treated, the authors determined that the incidence of thrombophlebitis in the mothers was not increased (owing to the increased plasma prothrombin) in the treated cases, and that the giving of vitamin K had no effect on maternal blood loss. Concerning the infants born in the two series, the former, treated with vitamin, showed 6 deaths, a mortality of 1.5 per cent; the latter, or control series, showed 16 deaths, a mortality of 4.1 per cent. Only 1 fatal case in the treated series showed hemorrhage (sub-arachnoid) at autopsy, whereas 9 of the 16 fatal cases in the control series showed hemorrhage at autopsy, 3 of which were cerebral, and 1 of which showed the classic syndrome of hemorrhagic disease of the newborn.

The following well-founded deductions are indicated in the authors' study:

Hemorrhagic diathesis in the newborn represents simply an extreme degree of hypoprothrombinemia which all newborn infants exhibit to a certain extent and in various gradations.

Unless the plasma prothrombin level is extremely low, this hypoprothrombinemia may be without clinical manifestations.

If birth trauma, anoxia and other causes of bleeding are superimposed upon it, this prothrombin lack must necessarily play a part in the duration and therefore in the extent of the bleeding.

It seems that routine antenatal administration of vitamin K, properly timed, and with suitable dosage, will well-nigh eliminate so-called "hemorrhagic disease of the newborn." Certain types of cerebral hemorrhage, particularly small hemorrhages that ooze for a number of days, may be preventable by this procedure.

The trend of recent reports, therefore, indicates that vitamin K concentrate, or the synthetic substance, 2-methyl-1,4-naphthoquinone, is a promising agent to be used in the effort to reduce mortality among newborn infants. As stated by the Baltimore investigators, the triad of anoxia, trauma and hypoprothrombinemia must be considered as malignantly allied factors in the causation and

outcome of every case of bleeding in the newborn, whether cerebral or otherwise; and the hypoprothrombinemia is the one factor in this triad that is subject to prophylactic correction. From the therapeutic angle, however, the relative efficacy of administration of vitamin K and of transfusion of whole blood in cases of clinically evident hemorrhagic disease awaits elucidation.

**CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL**ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor***CASE 27051****PRESENTATION OF CASE**

A sixty-four-year-old man entered the hospital complaining of three attacks of upper abdominal distress.

Eight years before entry the patient had an attack of upper abdominal discomfort associated with general malaise, anorexia, nausea and vomiting. This lasted for four days, and gall-bladder studies at this time revealed a functioning gall bladder with a haziness of the shadow, "suggestive of sand." Except for slight gaseous eructation he was well until three years prior to admission, when he had a similar attack, which lasted for three weeks. X-ray studies were similar to those taken five years previously. At no time was there fever, jaundice or a change in the character of the stools. The third attack occurred six weeks prior to entry, and for the first time the patient noticed tenderness in the right upper quadrant of his abdomen. X-ray examination at this time showed an unusually large gall bladder filled with dense dye. There was an irregular-shaped area of calcification floating in the gall bladder, which sank to the bottom of the gall bladder in the upright position. There was no definite change in the size of the gall bladder after a fatty meal. Films of the gastrointestinal tract showed a small adhesive diverticulum in the middle third of the esophagus. The stomach showed no abnormalities; the pylorus opened readily. The duodenal cap showed marked swelling of its folds, but a definite crater was not demonstrable. There was no constant narrowing of the cap, and the remainder of the duodenum appeared normal. An x-ray film of the chest showed the diaphragm to be low in position, but normal in outline, with normal respiratory excursion. The heart shadow was slightly prominent in the region of the left ventricle; the aorta was slightly tortuous. The lung roots were normal in width and density, and the apical and peripheral portions of the lungs were clear. The lung markings in the basal portions were slightly prominent. An electrocardiographic recording showed normal sinus rhythm with a rate of 78, a PR interval of 0.16 second and a QR interval of 0.08 second; T₁ and T₂

were upright, T₃ flat and T₄ upright; left-axis deviation was well marked.

The upper abdominal discomfort and anorexia were still present at the time of admission. The patient lost 6 to 8 pounds in weight. In the past he had had frequent sore throats.

On examination the throat was reddened and edematous. Examination of the heart and lungs was negative; the blood pressure was 132 systolic, 72 diastolic. A definite sense of resistance with mild tenderness was present in the right upper quadrant of the abdomen.

The temperature, pulse and respirations were normal.

Examination of the urine was essentially negative. Examination of the blood showed a red-cell count of 5,100,000 with a hemoglobin of 17.5 gm. (photoelectric cell technic), and a white-cell count of 15,600 with 78 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 20 mg. per 100 cc., the serum protein 6.4 gm. per 100 cc., and the chloride 115.5 milliequiv. per liter.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. F. DENNETTE ADAMS: Customarily when I receive one of these protocols I spend hours trying to make a diagnosis. In this case I have spent even more time trying to avoid making one. At first glance this appears to be a simple case of gall-bladder disease—three attacks of upper abdominal distress with anorexia, nausea and vomiting, the last accompanied by tenderness and resistance in the right upper quadrant and presumptive roentgenologic evidence of stone in the gall bladder.

Yet a more careful analysis of the record introduces a not inconsequential element of doubt. The patient had very little discomfort in the first and second attacks. In none of the three was there pain characteristic of gallstone colic. Nor was there fever, pronounced tenderness or any other indication of acute gall-bladder infection. During the eight-year period he was always quite well between attacks. Complete interval freedom from symptoms is not inconsistent with chronic cholecystitis, yet a gall bladder diseased enough to cause three definite episodes might well be expected to create during the intervals at least a few spells of vague indigestion, flatulence or other minor digestive complaints. In the third attack the tenderness and resistance, in addition to the subjective symptoms, incline one to the diagnosis of gall-bladder disease, and in the pres-

ence of a positive roentgenogram, I should make that diagnosis.

But the roentgenologist's report clouds the issue. Before I ask Dr. Hampton to show the films let me speculate for a moment: the gall-bladder shadow is said to be large. A large gall bladder almost invariably results from one of two disorders—acute cholecystitis, especially when it is associated with stone in the cystic duct, a condition in which one expects definite systemic reaction, acute pain and tenderness, or tumor of the head of the pancreas or some other obstructive lesion (other than stone) of the common bile duct. Here progressive jaundice is the rule. In neither condition would one expect the gall bladder to fill with dye. It is impossible for me to explain to my satisfaction both adequate filling and enlargement of the gall bladder. They seem almost paradoxical. I hesitate to suggest that the films were wrongly interpreted, yet with due respect to our roentgenologists the fact remains that such unhappy circumstances can occasionally occur. A year or so ago on this same rostrum I attempted to account for an abdominal tumor reported by the roentgenologist, only to learn from Dr. Mallory that no tumor was found at autopsy. Perhaps Dr. Hampton can help us out with these films.

DR. AUBREY O. HAMPTON: Apparently the radiologist was interested in the duodenum, because he took an enormous number of films. I must say that in most of them the duodenum does not look very normal. There is not much doubt that the mucosa of the duodenum is thickened, but when it is filled completely it is smooth in outline. Here is one spot film that shows a little fleck of barium in the cap that might be something abnormal. This is the gall bladder. It is large and stays that way in all the films, and this shadow within it shifts in position, but remains in the gall-bladder shadow. I think that there is evidence of gall-bladder disease, with a stone, and that for some reason or other the gall bladder is dilated. I also happen to know the diagnosis in this case and cannot answer too many questions, but the radiologist asked for a re-examination of the duodenum because he was not satisfied.

DR. ADAMS: After viewing the films I must concede that the gall bladder is both well filled and large, but I do not know why. Nor can I account for the abnormality of the duodenum; the picture is not that of the secondary changes resulting from gall-bladder disease. One must therefore either disregard the gall-bladder enlargement and make a diagnosis of simple chronic cholecystitis with stone or, if one insists on accounting for the gall-bladder enlargement, conclude that

something may be partially obstructing the cystic duct. Perhaps that something is related to the duodenum. At any rate I believe that the roentgenologic findings in the duodenum cannot be thrown aside. The evidence is far from clear cut, but tumor may be found.

DR. WILLIAM B. BREED: May I ask Dr. Hampton about the Graham test when there is a stone obstructing the cystic duct?

DR. HAMPTON: There should be no increase in density because, of course, no dye enters the gall bladder. It is true, though, that a dilated gall bladder due to cystic-duct obstruction is sometimes visible on a plain film. I should think it would not be so dense as this one. I think that this gall bladder had dye in it, and that the cystic duct was open.

DR. ADAMS: Needless to say, the diagnosis of simple gall-bladder disease is one that I am trying to escape. I am not willing to stand on that alone. The enlargement of the gall bladder still worries me, and so does the roentgenologist's report concerning the duodenum. I am therefore going to add carcinoma of the duodenum to the diagnosis of chronic cholecystitis with stone. The former is rare, I know, but this clinical picture is also rare.

DR. HENRY W. FAXON: Would you consider pancreatitis? He had stones, a high white-cell count and a great deal of nausea and vomiting.

DR. ADAMS: My impression is that pancreatitis is usually secondary to a stone lodged in the ampulla of Vater. There is no evidence of common-duct stone in this patient, so that, in my opinion, pancreatitis is automatically excluded.

DR. HAMPTON: Would you agree if the radiologist said that the patient had a duodenal ulcer?

DR. ADAMS: Without a more clear-cut history, I should agree only if the roentgenologist could demonstrate a crater.

DR. TRACY B. MALLORY: Dr. Smith, you speculated a great deal about this case. Will you express an opinion?

DR. WILLIAM D. SMITH: I did not believe that this patient could have a duodenal ulcer because I have never known anyone who grew up with fewer dyspeptic symptoms than this man had—practically none. As Dr. Adams said, the patient never had any severe pain, just a mild discomfort never sufficient to keep him awake. One night he woke up feeling a bit uncomfortable, and took a couple of drinks of whisky and went back to sleep.

DR. RICHARD H. SWEET: I was privileged to see this patient with Dr. Walter Bauer before operation, and to operate on him. We talked the history over very carefully. We took the x-ray films

down and went over them with Dr. Richard Schatzki, who took them. He was puzzled by the duodenal findings but made no diagnosis, and when we asked whether or not there was an ulcer he said he did not know. He suggested another x-ray film. Dr. Bauer and I concluded that since the patient had had several x-ray examinations, there was no point in further repetition.

I operated, expecting to find gallstones, which perhaps were causing the type of gastric symptoms that gallstones cause at times, although in this case they were a little severer than usual.

DR. ADAMS: Dr. Smith, what did you make of the large gall bladder?

DR. SMITH: I did not know. If it was a stone in a big gall bladder I wondered why it did not empty. I asked Dr. Hampton if it could be due to obstruction of the cystic duct, and he said that he thought it could not be.

DR. MALLORY: Dr. Sweet, will you describe the operative findings?

DR. SWEET: Our preoperative diagnosis was correct, but only partly so, as Dr. Adams intimated. We were very much astonished to discover that the undiagnosed aspect of the case was an acute, almost completely perforated, duodenal ulcer. It was covered with a sizable plaque of fibrin, which was the only thing that kept the contents of the stomach and duodenum from entering the peritoneal cavity. I should have guessed that if we had palpated the patient rather vigorously ahead of time, or if it had gone a few more hours, this ulcer would have perforated. He had a gallstone and a large gall bladder. We therefore opened the gall bladder, removed the stone, closed the bladder and directed our attention to the perforating ulcer.

DR. ADAMS: Was it posterior?

DR. SWEET: No, it was anterior. Dr. Bauer, Dr. Mallory and I discussed the situation and finally decided to perform a resection, which went very smoothly.

CLINICAL DIAGNOSES

Cholelithiasis.
Chronic cholecystitis.

DR. ADAMS'S DIAGNOSES

Cholelithiasis.
Chronic cholecystitis.
Carcinoma of duodenum?

ANATOMICAL DIAGNOSES

Acute perforating duodenal ulcer.
Cholelithiasis.

PATHOLOGICAL DISCUSSION

DR. MALLORY: One must examine the microscopic slide to convince oneself how near to perforation this ulcer was. There is a deep funnel-shaped defect in the wall of the duodenum, passing down through the mucosa, submucosa, muscularis, and even the serosa. At its base there is a layer of fibrin 1.5 mm. in thickness, and even with minute examination not a fibroblast is to be found. If another gastrointestinal series had been done and the duodenum vigorously palpated once more, acute perforation would almost certainly have resulted. A case of this type is perhaps hardly a fair one to put up for differential diagnosis. The important decision was whether and when to operate, and fortunately, it was correctly made.

DR. HAMPTON: I think that the reason the diagnosis was missed was that in the so-called "compression films" there was no compression. The crater would have shown up plainly if it had been compressed. Perhaps there was too much tenderness.

DR. ADAMS: Is Dr. Hampton able to explain the large gall bladder?

DR. HAMPTON: We have seen similar ones from time to time without stone or anything else to account for them.

CASE 27052

PRESENTATION OF CASE

A thirty-one-year-old housewife was admitted to the hospital complaining of pain in the right shoulder and cough.

For about four or five years before entry the patient had intermittent attacks of nagging pain in the right shoulder. At times she was unable to lie on her right side because of a sense of oppression. There was dyspnea with moderate exertion, and a slight degree of orthopnea. During the nine-month period preceding her entry there was a gradual loss of 25 pounds in weight. For three months there was a mild cough, which was worse in the morning shortly after arising and was productive of a small amount of yellowish-white sputum. Two months before entry "electric treatment" was administered to her shoulder by an "Indian doctor." Subsequently she felt very much improved, and the pain in the shoulder and dyspnea disappeared. The weight loss continued, however, and she developed a heavy sensation in the right dorsal region. She entered another hospital, where x-ray examination showed a tumor in the right chest. A right thoracentesis produced thick yellowish fluid.

The past history was noncontributory.

Physical examination showed a rather pale, thin young woman in no acute discomfort. The neck veins were distended. The left border of the heart extended 1 cm. beyond the left midclavicular line. The sounds were regular, and there were no murmurs. The blood pressure was 120 systolic, 80 diastolic. From the midaxillary line on the right to the midsternal line and extending from the third rib downward there were dullness to flatness and diminished voice sounds. Tactile fremitus

to the trachea in the lateral view. There were several plaques of calcification within its periphery. The heart was not displaced, and the mass could not be separated from the right cardiac border. Slight transmitted pulsation was evident. The right border of the heart was visible neither during fluoroscopy nor on the film. The superior mediastinum was distinctly widened, and its border was concave laterally. The remainder of the chest was not remarkable.

FIGURE 1. *Photographs of X-Ray Films Showing the Ovoid Mass in the Chest.*
A = anteroposterior view; B = lateral view.

was increased. No rales were heard. The remainder of the examination was negative.

The temperature, pulse and respirations were normal.

Examination of the urine was negative. The blood showed a red-cell count of 4,900,000 with a hemoglobin of 75 per cent, and a white-cell count of 6600 with 74 per cent polymorphonuclears. A blood Hinton test was negative.

X-ray films of the chest showed a large ovoid mass adjacent to the right border of the heart and filling the greater portion of the right lower-lung and midlung fields (Fig. 1). In the lateral view the mass filled the anterior two thirds of the chest. The lower border of the mass touched the diaphragm, and its upper border extended above the level of the hilus. Its center lay slightly anterior

to the trachea in the lateral view. There were several plaques of calcification within its periphery. The heart was not displaced, and the mass could not be separated from the right cardiac border. Slight transmitted pulsation was evident. The right border of the heart was visible neither during fluoroscopy nor on the film. The superior mediastinum was distinctly widened, and its border was concave laterally. The remainder of the chest was not remarkable.

DIFFERENTIAL DIAGNOSIS

DR. RALPH ADAMS: Chronic pain in the shoulder in association with symptoms of visceral disease may itself be considered visceral in origin when local explanations are lacking. Visceral causes may be grouped as those that irritate the diaphragm or its serous coverings, either peritoneal and pleural, those involving the upper intercostal nerves, and those directly affecting the phrenic nerve.

A sense of oppression on lying down is common in diseases characterized by abnormal return flow of blood to the heart, such as right-sided failure with pulmonary congestion and constrictive peri-

carditis with increased venous pressure. Cerebral anoxemia from venous stasis is a common factor in these conditions, and the patient learns to stay comfortable by avoiding the horizontal position. A sense of oppression arising unilaterally, however, suggests a localized partial obstruction to blood flow and demands a more specific explanation.

The loss of 25 pounds in weight within a year is indicative of altered metabolism. Either the patient had stopped eating or there had appeared some catabolic factor such as cancer, tuberculous infection or thyrotoxicosis to account for the weight loss. Any one of the three might bring about a productive morning cough, the first by invasion of the bronchial mucosa or pressure on a bronchus, the second by parenchymal lung destruction and the third by pressure on the trachea or a main bronchus, if the goiter lay subinternally.

A heavy sensation in one side of the chest, if persistent, is only rarely imaginary, although adequate explanation frequently eludes careful investigation, and the passage of time may be required for the development of localizing signs. In this case the heaviness in the chest appeared late and was apparently due to an expanding lesion. Pleural effusion, tumors causing bronchial constriction and pneumothorax may produce the symptom of heaviness, and probably have been named in the order of frequency, although statistical proof is not at hand.

The physical examination was unquestionably colored by the report from the outside hospital of a tumor in the right chest and the presence of thick yellowish intrapleural fluid. Distention of the neck veins means increased pressure within the superior vena cava. A normal heart by examination, so far as data are given for interpretation, excludes pericardial and cardiac disease and leaves one free to follow the assumption that the superior caval compression was due to the tumor mass. Signs of dullness over areas normally occupied by aerated tissue indicate replacement of the latter by tissue of greater density and less air content than the normal lung. These are signs that might be found over lung infiltrated by tumor and devoid of air, over a mediastinal tumor displacing and compressing the lung or over an encapsulated empyema. The absence of rales is not conclusive, but strongly suggests that the lung is not intrinsically diseased. Intrapulmonary disease sufficient to produce the other signs recorded could scarcely exist without producing rales.

The x-ray films described afford additional valuable evidence, and support the impression obtained from the history and the physical examination that the lesion is outside the lung and in

the mediastinum—in fact, in the anterior mediastinum.

Its position is medial to that which an empyema could occupy without rupture into the mediastinum, and the absence of evidence of infection further excludes that unlikely possibility.

To recapitulate, a typical history is given of a slowly growing anterior mediastinal tumor, producing a progressive sequence of symptoms—namely, displacement of the phrenic nerve posteriorly, with symptoms referred to the shoulder, interference with venous return from above the heart, presumably from pressure, a sense of oppression when the pressure was aggravated by lying on the affected side, distention of the neck veins and a mild productive cough by pressure irritation of the lower trachea.

There remain only three diagnostic possibilities. One is substernal goiter. The low position in the chest does not exclude it, and there is at least one surgical specimen in the hospital material of a large goiter removed from its resting place on the diaphragm. The weight loss is consistent with goiter, but there is no history of hyperthyroidism and the pulse is normal. A nontoxic or colloid goiter of this size in the mediastinum without detectable signs in the neck or elevated basal metabolic rate is possible. The calcification noted could occur in thyroid tissue, but an exudate of thick yellowish fluid ought not to be present.

Another possible diagnosis is neurofibroma, a notorious stimulator of diagnostic guessing bees, but it rarely occurs in the anterior mediastinum, being usually found in the posterior region, lying in the costovertebral gutter, arising from intercostal or sympathetic nerves and sometimes eroding contiguous ribs by pressure.

Malignant tumors are not among the probabilities in this case because of the duration of symptoms, the relative health of the patient and the calcification within the slowly growing tumor walls. Teratoma is also excluded.

The final and only tenable diagnosis is dermoid cyst of the anterior mediastinum. In the absence of signs of effusion in the x-ray film, it seems likely that the thoracentesis was in effect a puncture of the cyst and that the turbid fluid obtained represented cyst contents. I should like to have had the opportunity to examine this fluid for the presence of cholesterol crystals and epithelial debris; if present, they would have confirmed my diagnosis.

CLINICAL DIAGNOSIS

Dermoid cyst of anterior mediastinum.

DR. ADAMS'S DIAGNOSIS

Dermoid cyst of anterior mediastinum.

ANATOMIC DIAGNOSIS

Dermoid cyst of anterior mediastinum.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The X-ray Department was reluctant to make a diagnosis of a dermoid cyst in this case because of the presence of calcification. We have, however, seen calcification in dermoids on other occasions. Dr. Adams's diagnosis was readily substantiated when the patient was operated on by Dr. Edward D. Churchill. The right pleural cavity was opened following subperiosteal resection of the fourth right rib. A large avascular cystic tumor was found in the anterior mediastinum projecting into and largely filling the right pleural cavity, displacing the middle and lower lobes backward and laterally. The

upper lobe was partially adherent. A plane of cleavage was found that permitted fairly easy enucleation except at the point of origin, which was just below the point of bifurcation of the trachea and about the superior vena cava.

The specimen that reached the laboratory was an unruptured cyst 20 cm. in circumference, with a wall varying from 2 to 4 mm. in thickness, which contained numerous thin calcified plaques 2 to 6 mm. in diameter. The cavity contained matted hair, and on microscopic examination the walls showed the characteristic skinlike structure of a dermoid.

The patient made a rapid postoperative recovery from the physical point of view, although the development of a postoperative psychosis somewhat delayed her discharge from the hospital.

COMMUNITY FUND

LAST week physicians were reminded that a challenge had been issued, since their quota for the Community Fund had been increased to \$20,500.

How is it going? At the end of the first week of the drive, January 24, a total of seventy-three doctors had given \$7000, which is an average of nearly \$100 per person. Twenty-four of this number made increases in their gifts over last year. These men are the leaders, and they also give generously of their time in many of the social agencies that the fund helps to support.

An interesting anecdote is worth recording here. One of these men said: "Well, here is the yearly collection of pledges for the fund. You know, I think we should look on this organization as a voluntary tax program in which we give to a

selected group whom we trust, to manage our community welfare." This expression contains the very essence of the objective in contributing to the Community Fund.

The community is looking for the financial support of the medical profession, and only five days remain.

SOCIAL HYGIENE DAY

THE designation of February 5 as Social Hygiene Day is particularly significant this year, since large numbers of young men will be gathered together in cantonments and in the areas where war industries are located. It is a well-recognized fact that when young men are collected in camps or in industrial centers, syphilis and gonorrhea constitute a major hazard. During World War I a total of 7,004,818 days, equivalent to a year's actual absence from service of 22,300 men, was lost by the United States Army and Navy as the result of genitoinfectious diseases.

Although the Government plans to protect the health of its soldiers and sailors so far as possible, it cannot regulate their behavior when off duty. The health of workers in the war industries is even less controlled, and that of the civil population, so far as it is affected by contact with service men and workers, is regulated only when the identity of an infected person is made known to the local board of health.

During this critical period, the American Social Hygiene Association and its constituent state societies can be of the greatest help. A four-point program has been outlined, consisting of the following activities:

Through educational activities, such as films, literature, exhibits and lectures, to help soldiers, sailors, industrial workers and the population in general to understand the hazards of syphilis and gonorrhea.

To encourage the passage and enforcement of protective laws for the reduction of prostitution and the prevention of delinquency, especially in areas of concentration of armed forces and of defense-industry workers.

To promote and aid in the establishment of facilities for early disinfection and other preventive measures.

To urge provision of adequate diagnosis, treatment and isolation, particularly where local facilities are inadequate to cope with the situation.

This program is an amplification of the work that has been carried on for some years by the Massachusetts Society for Social Hygiene and its adaptation to the particular needs arising from the concentration of young men in camps and industrial centers.

The situation is one that deeply affects the whole nation; it calls for co-ordinated action by all those organizations that are concerned with the public welfare. It is imperative that the members of the medical profession should be prepared to inform the public of the deleterious effect of genitoinfectious diseases on the efficiency of the nation's forces, and to spread the doctrine that control of these diseases is an important way to strengthen national defense.

MEDICAL EPONYM

GAUCHER'S DISEASE

"L'épithélioma primitif de la rate, hypertrophie idiopathique de la rate sans leucémie [Primary epithelioma of the spleen, idiopathic hypertrophy of the spleen without leukemia]" was the title of Philippe Charles Ernest Gaucher's (1854-1918) thesis for the degree of doctor of medicine from the University of Paris in 1882. The following translation is the résumé of his conclusions:

There is a peculiar kind of primary and idiopathic hypertrophy of the spleen to which I propose to give the name "*primary epithelioma of the spleen*" in accordance with its histologic characteristics.

The *clinical features* of this disease are: gradual, progressive enlargement of the spleen to a considerable degree, with associated spontaneous pains and various compression phenomena, hemorrhage (epistaxis, purpura and hemorrhagic gingivitis), occasionally jaundice resultant on secondary enlargement of the liver, without leukemia, intermittent fever or ascites, and terminating in a marked cachexia.

The *anatomic feature* is a very large spleen (4770 gm.) of uniform and even development, its surface smooth and regular, the color and form almost normal, but hard and sclerotic.

The *histologic characteristics* are: complete replacement of the normal splenic elements by large, epithelial cells, irregularly rounded or polyhedral in shape, nucleated, and enclosed in the normal interstices of the hyperplastic splenic reticulum; interstitial hemorrhages; complete disappearance of the Malpighian corpuscles; partial disappearance of the blood vessels.

CONGESTIVE FAILURE DUE TO MITRAL STENOSIS AND TREATED BY THERAPEUTIC ABORTION

Mrs. R. E., a thirty-nine-year-old para IV, was admitted to the hospital on June 21, 1940, complaining of shortness of breath and epigastric fullness. She was in the sixth month of her pregnancy.

The family history was noncontributory. The patient's past history included measles and typhoid fever, for which she was kept in bed five or six weeks. There was no history of rheumatic fever or chorea. The first two pregnancies went to full term with normal deliveries. The third pregnancy, in 1936, was complicated by decompensation in the third month. After consultation, a therapeutic abortion was performed, following which the patient made a complete recovery. Catamenia began at the age of twelve, were regular with a thirty-day cycle and lasted five days without pain. The last period began on December 20, 1939, making the expected date of confinement, September 27.

The patient had been feeling fairly well since the onset of this pregnancy except for swelling of the feet and ankles and some breathlessness on exertion during the month preceding entry. On June 17, she began to have considerable dyspnea, coughing and a painful sensation across the lower chest and epigastrium. She was admitted to the hospital four days later.

In view of the cardiac condition, a medical consultation was held. The consultant's note reads as follows:

The patient has had well-compensated valvular heart disease, but congestive failure has now developed. Physical examination shows tachycardia and slightly accentuated heart sounds, with definite diastolic and presystolic murmurs at the apex and a slight early diastolic murmur at the left sternal border; there are rales at bases of the lungs and definite pitting edema over the sacrum and ankles. The blood pressure is 180 systolic, 85 diastolic. Diagnoses: mitral stenosis, hypertension and congestive failure. Immediate digitalization is advised, and if after a few days, the patient shows some improvement, a therapeutic abortion should be performed.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

On July 1, under cyclopropane anesthesia, a therapeutic abortion was completed by means of abdominal hysterotomy. A living premature baby was delivered, who died forty hours later. Both tubes were ligated at the time of operation. Convalescence was essentially afebrile, and the patient was discharged on the thirteenth postoperative day.

The patient's general condition at discharge was good. There was no edema; the blood pressure was 118 systolic, 74 diastolic, the pulse 88. There was no dyspnea or signs of cardiac embarrassment.

Comment. The question arises whether the present pregnancy should have been terminated, like the previous one, by early therapeutic abortion. That this would have been the wiser procedure is shown by the decompensation that subsequently developed. However, the advisability of interrupting pregnancy in a cardiac patient who has been allowed to go on to such a late stage is questionable. Some authorities advise hospitalization and carrying the patient to term. However, in spite of rules and in spite of statistics, each case should be decided on its own merits. The result in this case reasonably justified the treatment.

MEDICAL POSTGRADUATE EXTENSION COURSES

The following sessions, given by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, have been arranged for the week beginning February 2:

MIDDLESEX EAST

Tuesday, February 4, at 4:15 p.m., at the Melrose Hospital, Melrose. Diagnosis and Treatment of Minor Lesions of Rectum and Anus. Instructor: Neil W. Swinton. Walter H. Flanders, *Chairman*.

MIDDLESEX SOUTH

Tuesday, February 4, at 4:00 p.m., at the Cambridge Hospital, Mt. Auburn Street, Cambridge. Obstetric Complications: With case histories and clinical problems. Instructor: M. V. Kappius. Dudley Merrill, *Chairman*.

NORFOLK

Thursday, February 6, at 8:30 p.m., at the Norwood Hospital, Norwood. Acute Abdominal Pain: Its interpretation and management. Instructor: Richard B. Cattell. Hugo B. C. Rierner, *Chairman*.

NORFOLK SOUTH

Monday, February 3, at 8:30 p.m., at the Quincy City Hospital, Quincy. Dermatitis and Eczema. Instructor: Jacob H. Swartz. David L. Belding, *Chairman*.

SUFFOLK

Thursday, February 6, at 4:30 p.m., in John Ware Hall, Boston Medical Library. Dermatitis and Eczema. Instructor: John G. Downing. Reginald Fitz, *Chairman*.

DEATHS

CROFTS — NICHOLAS M. CROFTS, M.D., of North Adams, died September 17, 1940. He was in his seventy-sixth year.

Born at Carlton Place, Canada, he received his degree from the Baltimore Medical College in 1898, and in 1914 took a postgraduate course at the University of Maryland.

Dr. Crofts was a fellow of the Massachusetts Medical Society and of the American Medical Association.

A daughter and one brother survive him.

MAGEE — EDWARD J. MAGEE, M.D., of Danvers, died January 20. He was in his seventy-ninth year.

Born in Oswego, New York, he attended Ottawa College and Villanova College and received his degree from the College of Physicians and Surgeons of Boston in 1891.

Dr. Magee was a member of the Massachusetts Medical Society and the American Medical Association, and was on the staff of the Hunt Memorial Hospital in Danvers.

A daughter survives him.

MISCELLANY

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR DECEMBER, 1940

DISEASES	DECEMBER 1940	DECEMBER 1939	FIVE YEAR AVERAGE*
Anterior poliomyelitis	0	6	6
Chicken pox	1679	1511	1442
Diphtheria	9	20	26
Dog bite	539	578	539
Dysentery, bacillary	3	27	12
German measles	48	26	62
Gonorrhea	294	335	470
Lobar pneumonia	406	396	469
Measles	1166	1082	964
Meningococcus meningitis	7	1	6
Mumps	597	347	603
Paratyphoid B fever	1	2	3
Scarlet fever	642	412	722
Syphilis	376	433	454
Tuberculosis, pulmonary	326	284	259
Tuberculosis, other forms	30	28	28
Typhoid fever	6	5	7
Undulant fever	5	2	5
Whooping cough	1160	498	807

*Based on figures for preceding five years

RARE DISEASES

Anthrax was reported from: Haverhill, 1; Peabody, 1; total, 2.

Diphtheria was reported from: Boston, 1; Chelsea, 1; Fall River, 5; Reading, 1; Waltham, 1; total, 9.

Dysentery, bacillary, was reported from: Boston, 2; Watertown, 1; total, 3.

Meningococcus meningitis was reported from: Beverly, 1; Boston, 1; Milford, 1; Orange, 1; Swampscott, 1; Worcester, 2; total, 7.

Paratyphoid B fever was reported from: Springfield, 1; total, 1.

Pfeiffer bacillus meningitis was reported from: Orange, 1; Spencer, 1; total, 2.

Septic sore throat was reported from: Boston, 5; Malden, 2; Medford, 1; Melrose, 1; Merrimac, 1; Montague, 1; New Bedford, 1; Quincy, 1; Taunton, 2; Wrentham, 2; total, 17.

Trachoma was reported from: Boston, 1; New Bedford, 1; total, 2.

Trichinosis was reported from: Boston, 1; total, 1.

Typhoid fever was reported from: Boston, 1; Lawrence, 1; Lexington, 1; New Bedford, 1; Quincy, 1; Waltham, 1; total, 6.

Undulant fever was reported from: Acton, 1; Amherst, 1; Chelmsford, 1; Lynnfield, 1; Petersham, 1; total, 5.

Chicken pox, measles and pulmonary tuberculosis were reported above the five-year averages.

Diphtheria, typhoid fever, paratyphoid fever, anterior poliomyelitis, bacillary dysentery, German measles, lobar pneumonia and scarlet fever were reported below the five-year averages.

The incidences of meningococcus meningitis, mumps, tuberculosis (other forms) and undulant fever were not remarkable.

Whooping cough showed unusually high incidence.

Dog bite was reported at a record high figure for the fifth consecutive month. Animal rabies was reported from Leicester, Spencer and Worcester, which are adjacent to one another.

TUBERCULOSIS EXHIBIT

Last year the National Tuberculosis Association built for the annual meeting of the American Medical Association an illuminated exhibit on "Morphologic Biology of Tuberculosis." A new and better exhibit is being built for the Cleveland meeting. It may be borrowed by any medical society whose meeting is to be held later than June 10, 1941. Those who are interested should communicate with the Massachusetts Tuberculosis League, Little Building, Boston.

MAINE NEWS

PANEL DISCUSSIONS AVAILABLE TO COUNTY MEDICAL SOCIETIES

The following panel discussions have been made available for presentation before county medical societies by the Committee on Graduate Education:

Coronary Disease. E. H. Drake, M.D., Portland, chairman.

Complications of Pregnancy. R. B. Moore, M.D., Portland, chairman.

Disease of the Liver and Bile Passages. J. Gottlieb, M.D., Lewiston, chairman.

Endocrine Dysfunction. James Carswell, M.D., Camden, chairman.

Syphilis. O. R. Johnson, M.D., Portland, chairman.

Chemotherapy. F. T. Hill, M.D., Waterville, chairman.

Appendicitis. I. M. Webber, M.D., Portland, chairman.

NEW MEMBERS

The following physicians have recently been admitted to membership in the Maine Medical Association:

James M. Parker, Portland.

Henry B. Finks, Portland.

Dexter J. Clough, 2nd, Bangor.

Hans Schurman, Dexter.

John E. Smith, Bangor.

MOTOR-VEHICLE DEATHS FOR 1940

Motor-vehicle deaths in one hundred and fifty-eight major cities increased 3.4 per cent in 1940 over the previous year, according to reports made public recently by Director William L. Austin, Bureau of the Census, Department of Commerce. Deaths for 1940 totaled 8441, compared with 8162 in 1939. These percentage increases are based on provisional figures for 1940 and 1939.

Considering only those deaths in each city due to motor-vehicle accidents occurring within the city limits, the 1940 reports showed a total of 5799 deaths. This figure is an increase of 68 deaths, or 1.2 per cent, over the 5371 deaths reported for the same cities in 1939. The increase in the total is reflected in the individual cities, seventy-six of which showed an increase in the number of deaths over 1939; seventy-one showed a decrease, and eleven cities had the same number.

Eight of the cities having populations of 500,000 or more and showing increases in the number of deaths occurring within the city are: New York City (1.0 per cent); Detroit (13.5 per cent); Los Angeles (12.0 per cent); Baltimore (2.4 per cent); St. Louis (91.5 per cent); Boston (7.1 per cent); Pittsburgh (11.6 per cent); and Milwaukee (25.0 per cent). Five cities having similar populations and showing decreases from the 1939 figures are: Chicago (4.4 per cent); Cincinnati (13.0 per cent); Washington (24.4 per cent); San Francisco (13.2 per cent); and Buffalo (22.9 per cent).

CORRESPONDENCE

PHYSICIAN WANTED AT ST. GEORGE, MAINE

To the Editor: The town of St. George is without a physician. Do you know some good physician who would be interested in locating here? The nearest physician we can call lives in Thomaston or Rockland, fifteen or twenty miles away.

M. J. HARRIS.

Tenants Harbor, Maine.

ENGLAND IN THE FALL OF 1940

To the Editor: I believe the following letter from Sir James Purves-Stewart will be of interest to the readers of the *Journal*. It is written from his lighthouse home on the south coast of Sussex, a most exposed position.

HENRY R. VIETS, M.D.

* * *

Belle Tout Lighthouse,
Beachy Head, Sussex,
November 4, 1940.

Dear Dr. Viets:

Your very kind letter of August 31 took many weeks to arrive, but ultimately reached me here a couple of weeks ago. I waited until today, when the reprint of your kindly review of "Sands of Time" arrived, before replying to it. I am glad that the book made a favorable impression on you.

We in England are at the most historic phase of our history. During the last six months, we have had to confront one catastrophe after another. In May the allied forces, which had occupied Narvik in Norway, were withdrawn, to face-up Hitler's sudden "protection" of Denmark and his unprovoked attack on Holland and Belgium. Then the Germans out-flanked the Maginot line, on which the faith of the French had been blindly fixed.

and proceeded to sweep into Belgium from the south as well as the west. Holland threw up the sponge, after four days. Then in Flanders, after a courageous allied Franco-Anglo-Belgian start, Leopold of the Belgians suddenly surrendered, without notifying his allies, thereby laying the left flank of the allied army wide open to the enemy. The Germans naturally thought they had us at their mercy, surrounded on three sides. But the English, and part of the French army, fought their way back to the coast at Dunkirk, where nine tenths of their army of 350,000 men were successfully evacuated by the British fleet, assisted by every available smack, fishing boat and pleasure-boat on the east coast of England. All this was under a withering hail of artillery and tank guns, like wise air plane bombs, from the enemy. The English troops made a stubborn resistance. Our air planes drove off the Germans with comparative ease, whenever they got in touch, our infantry cut through the German battalions like straw, being better than them, man for man, every time. Our troops hated re-embarking, but the strategic position was hopeless and we were outnumbered six or seven times over. Anyhow the withdrawal, skilful though it was, was a major setback for us, and one which we are grimly determined to avenge, when the time comes.

Then, worst of all, France, betrayed by her corrupt government, threw up the sponge, and left Great Britain to carry on alone. Ever since, the puny politicians at Vichy have been grovelling to the German high command. Petain has become a confirmed boot-licker of his conqueror. His speeches, to his own countrymen, have been ignoble in their servility, entirely unlike what one would have expected from the hero of Verdun in 1917.

England is now the only European power that stands between Hitler and world domination. We are determined to fight, to the last man, the last cartridge, and the last ration. But since we have been alone, the tide has begun to turn. Every month we feel more optimistic. One side or the other must be crushed, and crushed permanently. It won't be England. We are full of enthusiasm and keenness. Hitler's threat of invasion, and the partial attempt which he started to make in September, has not materialised. We hoped it would. Every man here was and still is, on tip-toe, eager to get at the enemy and to ensure that not one of the invaders will ever see his Vaterland again.

I myself joined up with the Home Guard, doing rifle practice, bombing tactics, etc., and wearing khaki uniform (for the third time in my lifetime). Of course I was over age, but I managed to have a failure of memory when stating my age, and was not only accepted but placed in charge of the medical arrangements for casualties in our local battalion. Since then after three months service, under false pretences, I have been combed out. Had I been placed in the dock as a criminal, I should have pleaded guilty, and thrown myself on the mercy of the court.

Recently I have been appointed as liaison officer with the Foreign Relations Department of the British Red Cross, and last week completed a tour of inspection of prisoners of war camps in England. Most of these prisoners are young airmen. It is interesting to observe their mentality. They are officers, but not officers and gentlemen. They are more like the gangster type. And they have abnormal tastes, at times. The amount of face cream bought by German airmen officers is curiously large. If lip-stick were available, they would buy that, too. Several have been brought down with painted lips

and cheeks. This German type of vice is interesting to the medical psychologist.

By this time our airmen have clearly demonstrated their superiority over the Germans. The enemy losses in air fights are three or four to one of ours. So we have command of the air over England, although the Germans send over air planes at night, to destroy London, Liverpool, Eastbourne, Dover and other towns. They claim that they only attack military targets. These include St Paul's cathedral, St James's, and Buckingham and Kensington palaces, the mediaeval Elizabethan Temple of the law courts, and innumerable hospitals and rows of private houses. The German embassy in London, by accident, has been destroyed by their own bombs. But every man, woman and child is a military target to the German airman. We recognise this, and don't grumble unnecessarily.

Meanwhile our navy commands the seven seas. And when our growing supply of air planes, from Canada and the U S A, attains anything like equality in numbers with the enemy, we shall then disinfect the skies of Europe from the Nazi stench.

Don't be sorry for us. As Shakespeare says in *Henry V*

If we are mark'd to die, we are now
To do our country loss, and if to live,
The fewer men, the greater share of honour.

Here in our little lighthouse, on the Sussex cliff edge, we are daily witnesses of bombings and aerial dog fights. So far, our lighthouse has not been hit, although many bombs have fallen close by. We have sandbagged our roof against incendiary bombs. The main tower, of granite, six feet thick, will probably stand up to a direct hit, even from a heavy shell. But we are determined to stay put. If we are to be bombed, we shall be bombed comfortably in our own home, rather than wandering over the country, seeking for some unattainable safe place.

If only your polyethnic U S A would come in, too, it would hasten the victory—even if not a single American soldier embarked for Europe.

With kind regards to yourself and all my American friends and colleagues

Very cordially yours,

J PURVES-STEWART

The German radio informs us that we are already completely beaten, and it is only our congenital stupidity which prevents us from realising it.

MASSACHUSETTS STATE GUARD

A number of doctors are needed for duty as medical officers with the new Massachusetts State Guard which is now being formed. This volunteer organization will function in place of the Massachusetts National Guard, which is being inducted into federal service. It will be trained to cope with any emergency situation that might occur within the Commonwealth and which might overtax the capacities of civilian organizations.

A doctor, after receiving his commission, at the outset will have to devote a certain number of evenings to the examination of recruits, and thereafter will be expected to give one evening a week to drill, training and other routine duties. Full time service will be required only in the event of some emergency, and will be limited to within the State.

The requirements of the physical examination are not strict. Previous military experience is desirable but not a necessary prerequisite. It is not expected that this duty

will interfere materially with one's private practice. Any interested medical men will please communicate promptly with the undersigned, stating briefly their age, qualifications, and previous military experience, if any. Outside the Greater Boston area, there is need for one or more men in or near Brockton, Fall River, Framingham, Holyoke, Lawrence, Lynn, New Bedford, Pittsfield, Plymouth, Salem, Springfield and Worcester.

RICHARD H. MILLER, M.D., *Chief Surgeon.*

264 Beacon Street,
Boston.

REPORT OF MEETING

NEW ENGLAND PEDIATRIC SOCIETY

A regular meeting of the New England Pediatric Society was held at the Longwood Towers on October 30, 1940, with Dr. R. Cannon Eley presiding. Dr. Philip M. Stimson, of the Willard Parker Hospital in New York City, spoke on "Certain Aspects of the Common Contagious Diseases." Only the more important practical and controversial problems concerned with measles, mumps, chicken pox, rubella, scarlet fever, diphtheria, pertussis and poliomyelitis were discussed.

With regard to prevention, Dr. Stimson stated that active vaccination is definitely indicated for diphtheria and strongly advised for pertussis, particularly in infancy. An analysis of statistics from Cleveland, where 10 per cent of the children received Sauer vaccine, and neighboring Shaker Heights, where 75 per cent were vaccinated, revealed that the incidence of pertussis declined 11 per cent in the former and 83 per cent in the latter community, as compared with the prevaccination era. And there also seems to be evidence that the severity of the disease is diminished, even if total protection is not afforded. The total dose may now be as high as 100,000,000,000 organisms, and the question of a "refresher" vaccination each year during childhood is being considered.

Dr. Stimson considers scarlet fever vaccination to be effectual but not necessary or feasible except in asylums, in families in which scarlet fever has appeared, and in the medical and nursing professions.

An interesting situation has now arisen as the result of the widespread adoption of diphtheria vaccination; young adults are less exposed to the disappearing disease, and there is an increase in the percentage of susceptibles as shown by statistics. It was advised, therefore, that non-immune young adults receive two doses of alum-precipitated toxoid, with an interval of one month between injections. The Schick relapse rate, interestingly enough, has been found to be three times as high in those with the disease as in the vaccinated group.

Passive immunization is accepted for scarlet fever and diphtheria, whereas the use of convalescent serum in whooping cough is believed to confer at least a partial immunity for two or three weeks. This method of attack is particularly recommended for very young infants, who would fail to respond to active immunization.

So far as the virus infections are concerned, Dr. Stimson said that chemotherapy has so far proved inefficacious; that passive immunity with serum may be conferred when there is a generalized circulation of the causative agent, as in measles and mumps; that this form of prophylaxis is of no avail once the virus has become intracellular; that active immunity with dead or inactivated virus is ineffective; and that the immunity resulting from contracting the disease is lasting and of humoral and cellular form—except in herpes and influenza.

Further prophylactic possibilities are now being developed by the Dicks, who are working on a pill form of toxin for scarlet fever, and by experiments concerning the effect of chorioallantoic extracts on the virus of measles.

Diagnostic problems were next discussed. It has been found that measles usually occurs in biennial epidemics. Measles is not spread by its complications, so that a patient may be considered safe five days after the rash. The blood of measles patients is contagious, at least during the latter half of the incubation period, but Dr. Stimson stated that this does not mitigate against the pooling of such blood with others for "bank" purposes.

Rubella is rare except in epidemics and should be diagnosed with caution. Roseola infantum also is of importance in the differential diagnosis of measles. It occurs at two to three years of age and is ushered in by three days of unexplained fever with a morbilliform rash appearing after the fever has fallen and then starting on the body and being unaccompanied by Koplik's spots or coryza.

Chicken pox has been found to break out in epidemic form about two weeks following herpes zoster.

Diphtheria should probably be diagnosed clinically in most cases and should be corroborated by cultures. The use of a 2 per cent aqueous solution of potassium tellurite, which causes a blackening of the membrane, has been shown to result in too many false positive reactions to make it reliable, although a negative test rules out diphtheria fairly well. Clinically in diphtheria there is no erosion or ulceration but only a piling up of tissue. In the presence of ulceration, syphilis should be suspected if pain is absent; Vincent's angina, if the lesion is painful; and agranulocytic leukopenia, if prostration is marked. The electrocardiogram is useful in the diagnosis of late cardiac involvement. In mild cases there may be only an inverted T wave, but this should suffice to keep the patient in bed as long as two months. Eventual complete recovery is the rule unless death ensues.

Mumps occurred in one twentieth of the white and one sixth of the colored soldiers in the United States Army during World War I and was the third most important disease for loss of time. The virus probably enters by way of the nasopharynx into the bloodstream and then lodges in the glandular system, particularly the parotid glands. Meningitis and orchitis may occur at any stage, with or without parotitis. The height of the fever depends on the pressure to which the inflamed tissues are subjected. Sterility has been found a rare sequela because of the infrequent bilateral or complete involvement of the testes. Early incision of the testis was advised to lower the temperature, relieve the pain and prevent the danger of sterility.

In regard to treatment of these diseases, Dr. Stimson warned of the need for careful evaluation of statistics and clinical impressions, for the causative agent may vary in virulence and the course may be variable. The mortality from whooping cough at the Willard Parker Hospital, for example, decreased from 8 to 2 per cent on the same regimen. The importance of preventing cross and secondary infections was stressed, and the suggestion was made for less crowding in children's wards and better nursing technic. Isolation is usually based on the premise that there are no airborne epidemics and that a cough carries only five feet. Yet streptococci have been shown to exist in viable form in dust for twenty-four hours, and it is possible that several other organisms may do likewise. The use of ultraviolet light for air sterilization has been found to give encouraging results. The inoculation of all admissions to children's wards with convalescent or

adult serum or with placental extract has been suggested

The prevention of the spread of chicken pox remains an enigma. For treatment daily baths without rubbing were advised, and the immediate removal of all plaster casts and adhesive tape was strongly urged.

Scarlet fever is of variable severity, as shown by statistics from different countries and localities. Human convalescent serum in doses of 40 to 100 cc within twenty-four hours has been found beneficial, whereas modified horse serum, which gives reactions in less than 10 per cent of cases, has been shown to be equally effective and cheaper. Its use has been particularly advised for severe, toxic cases. Sulfanilamide, if administered early, may diminish the complications, for it guards against the streptococci of cross infections if not against those of scarlatina itself.

Convalescent serum decreases the number of cases and severity of measles if given more than twenty-four hours before the eruption. This is the only instance of effective serum therapy against a virus. The complicating pneumonias usually respond to chemotherapy, since they are streptococcal or mixed in etiology. Those of virus origin do not respond.

The pneumonia of pertussis should be treated as dictated by the culture, but the results with chemotherapy are not so good as in measles. To decrease the cerebral anoxia of the spasms and the resulting convulsions, oxygen has been found beneficial. The use of Kreuger vaccine for ten to fourteen days is expensive and hard on the patient in view of its questionable value in decreasing the severity of individual spasms.

In treating diphtheria, not less than 10,000 units of antitoxin are administered immediately intramuscularly; the use of more than 25,000 units intramuscularly and the same amount intravenously is rarely necessary. In toxic patients 5 to 10 per cent glucose is given intravenously to combat the decrease of liver glycogen. Laryngeal diphtheria is treated by aspiration rather than intubation. Serum reactions are being encountered in fewer cases. Histaminase is still unproved as an antidote, but Dr. Stimson stated that only very rarely is one unable to administer antitoxin following proper precautions. The use of a loose tourniquet and ephedrine was suggested, for patients thought to be serum sensitive, the injections being made in the anterior thigh, otherwise deep in the buttock.

More streptococcal throats are now being seen, and the early use of tracheotomy in cases of laryngeal obstruction instead of the former nonoperative regimen has resulted in the saving of 70 per cent of serious cases.

Investigations in poliomyelitis have accomplished little. A considerable incidence of the virus has been found in the stools, even of normal persons, a fact which presents the problem of whether the alimentary rather than respiratory tract is not the mode of entrance. The possibility that epidemics are started by food, water and other human hosts is becoming more real. The best protection at present, therefore, probably lies in proper personal hygiene, the prevention of fatigue, pasteurization of all milk, the boiling of water, and the barring of public swimming and the performance of tonsillectomies during an outbreak. Treatment should consist in complete rest in any illness during an epidemic. A patient should not be moved even to a hospital, unless a respirator is necessary. After diagnosis no muscles should be allowed to be stretched and no serum need be given. Ten per cent glucose may aid toxic patients, and massive doses of thymine chloride are possibly worth trying.

The discussion was opened by Dr. Conrad Wesselhoeft, who suggested the mixing of urban and rural recruits in

training camps to decrease the incidence of measles and mumps, and the use of convalescent serum for nonimmune contacts. The orchitis of mumps rarely occurs before puberty. Early incision is reserved for severe cases to relieve pain, to lower the fever and to save the testis from pressure atrophy. Ovaritis may occur before puberty and is usually accompanied by a vaginal discharge, moderate pain and an elevated temperature. In adults the temperature may reach 106°F and may be accompanied by chills. Atrophy is lacking because of the absence of a confining capsule.

Dr. Edwin H. Place of the Boston City Hospital, defended scarlet fever immunization. He stated that it does prevent the disease if properly used and that the main question concerns the prevention of toxic manifestations when the bacteria are uninfected. The complications of the latter can be minimized by adequate chemotherapy. Dr. Place decried the illogical practice of immunizing the medical profession and children in asylums and then allowing those on the fringe to go unprotected. He stated that the danger of immunization is highly overrated and that it must be classed merely as an unpleasant procedure.

Dr. Place warned against smallpox vaccination in dermatitis except in emergencies, because of the danger of eczema vaccinatum. Although dressings are inadvisable over vaccinations according to public health authorities, Dr. Place stated that proper light dressings prevent spread of the vaccine and the development of secondary infection.

Dr. Stimson closed the discussion with the observation that nurses may need as many as ten injections of toxin to get a permanently negative Dick test. He warned against diagnosing rubella except in epidemics and urged the discarding of the confusing name of German measles. In regard to the development of severe diphtheria in posttonsillectomy cases, —a rare danger,—he urged that the surgeon know the patient's state of immunity to diphtheria to be sure that he is not operating on a susceptible carrier.

NOTICES

ANNOUNCEMENT

CLIFFORD C. FRANSEEN, M.D., announces the removal of his office from 195 Pilgrim Road, Boston, to 1101 Beacon Street, Brookline.

NEW ENGLAND SOCIETY OF ANESTHESIOLOGY

The February meeting of the New England Society of Anesthesiology will be held in the Dowling Surgical Building, Boston City Hospital, on Tuesday, February 11, at 8 p.m.

PROGRAM

Rectal Evipal Dr. H. B. MacEwen
Anesthesia for Ludwig's Angina Dr. P. Marcus

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and staff meeting of the New England Hospital for Women and Children will be held on Thursday, February 6 at 7:15 p.m. in the classroom of the nurses' residence. Dr. Z. Eileen Taylor will speak on "Coagulation Defect of Menstrual Blood."

BOSTON SOCIETY OF BIOLOGISTS

There will be a meeting of the Boston Society of Biologists on Wednesday, February 19, in the lecture room, Eastman Building, East Wing, Massachusetts Institute of Technology, at 8 p.m. Dinner will be served in the Silver Room, Walker Memorial Building, at 7 p.m.

PROGRAM

A New Projection Oscillograph for the Observation of Electrical Potentials in Tissues. Dr. J. Warren Horton.

Proliferation-Promoting Factors (Wound Hormones) from Injured Cells. Dr. John R. Loofbourow.

Physiologic Effect of Decreased Body Temperature in Human Beings. Dr. John H. Talbott.

HARVARD MEDICAL SOCIETY

There will be a meeting of the Harvard Medical Society on Tuesday, February 11, in the amphitheater of the Peter Bent Brigham Hospital at 8:15 p.m. Dr. Soma Weiss will preside.

PROGRAM

Presentation of cases.

Pneumonia. Dr. Maxwell Finland.

Beginning with the February 11 meeting, the Harvard Medical Society will meet on the second Tuesday of each month rather than bimonthly as in the past.

ROBERT BRECK BRIGHAM HOSPITAL

There will be a staff meeting of the Robert Breck Brigham Hospital on Tuesday, February 11, in the hospital, 125 Parker Hill Avenue, Boston, at 7:45 p.m.

PROGRAM

The Present Status of Physiotherapy in the Treatment of Chronic Arthritis. Dr. Arthur L. Watkins. Discussion by Drs. Robert B. Osgood and Hallowell Davis.

Physicians and medical students are cordially invited to attend.

WALTHAM MEDICAL MEETING

There will be a clinicopathological staff conference of the Metropolitan State Hospital on Thursday, February 6, at 8 p.m. A case of amyotrophic lateral sclerosis will be presented by Drs. Clementine McKeon and Richard C. Wadsworth. It will be discussed by Dr. James B. Ayer.

All interested physicians are cordially invited to attend.

FELLOWSHIP OPPORTUNITIES

A limited number of fellowships have been provided by The Commonwealth Fund and other sources for extramural training in psychiatry, especially that of children. These fellowships are to be administered by the National Committee for Mental Hygiene, through whom fellows are to be assigned for one or two years to a selected child guidance clinic, the term and plan of the fellowship to be determined by the peculiar needs of the fellows. Candidates for fellowship should have had at least two years of psychiatry in an approved mental hospital, in addition to other qualities fitting them for extramural service. These fellowships come in response to a definite paucity of personnel in this field. Accordingly, other conditions, such as age, sex and marital status, must be governed by individual cases and by the nature of current demand. Re-

quests for further information about these fellowships, and applications therefor, should be addressed to Dr. Milton E. Kirkpatrick, National Committee for Mental Hygiene, Room 916, 1790 Broadway, New York City.

ELLA SACHS PLOTZ FOUNDATION

During the seventeenth year of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation, eighty-one applications for grants were received by the trustees, fifty-one of which came from the United States, the other thirty coming from fifteen different countries in Europe, Asia, North and South America. The total number of grants made during this year was twenty-three, one of these being a continued annual grant.

In the seventeen years of its existence the Foundation has made three hundred and ninety-four grants which have been distributed to investigators in Arabia, Argentina, Austria, Belgium, Brazil, Canada, Chile, China, Czechoslovakia, Denmark, Egypt, Estonia, Finland, France, Germany, Great Britain, Greece, Hungary, India, Iraq, Italy, Latvia, Lebanon, Netherlands, North Africa, Norway, Palestine, Poland, Portugal, Roumania, South Africa, Sweden, Switzerland, Syria, Venezuela, Yugoslavia and the United States.

In their first statement regarding the purposes for which the fund would be used, the trustees expressed themselves as follows:

For the present, researches will be favored that are directed toward the solution of problems in medicine and surgery or in branches of science bearing on medicine and surgery.

As a rule, preference will be given to researches on a single problem or on closely allied problems; it is hoped that investigators in this and in other countries may be found, whose work on similar or related problems may be assisted so that more rapid progress may be made possible.

Grants may be used for the purchase of apparatus and supplies that are needed for special investigations, and for the payment of unusual expenses incident to such investigations, including technical assistance, but not for providing apparatus or materials which are ordinarily a part of laboratory equipment. Stipends for the support of investigators will be granted only under exceptional circumstances.

In the past few years the policy outlined in the second paragraph has been neglected. During the present great need for funds, grants will be given in the sciences closely related to medicine without reference to special fields. The maximum size of grants will usually be less than \$500.

Applications for grants to be held during the year 1941-1942 must be in the hands of the Executive Committee before April, 1941. There are no formal application blanks, but letters asking for aid must state definitely the qualifications of the investigator, an accurate description of the research, the size of the grant requested and the specific use of the money to be expended. In their requests for aid, applicants should state whether or not they have approached other foundations for financial assistance. It is highly desirable to include letters of recommendation from the directors of the departments in which the work is to be done. Only applications complying with the above conditions will be considered.

Applications should be sent to Dr. Joseph C. Aub, Collis P. Huntington Memorial Hospital, 695 Huntington Avenue, Boston, Massachusetts, U. S. A.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, FEBRUARY 2

SUNDAY, FEBRUARY 2

14 p.m. Modern Advances in Surgery Dr Oliver W. Cope. Free public lecture Harvard Medical School Building D

14 p.m. Present Day Obstetric Practice Dr Alonzo A. Paine Public health lecture Cambridge Hospital Margaret Jewett Hall

MONDAY, FEBRUARY 3

12-15-15 p.m. Clinicopathological conference Peter Bent Brigham Hospital amphitheater

TUESDAY, FEBRUARY 4

12-15-15 p.m. Clinicopathological conference Peter Bent Brigham Hospital amphitheater

8-15 p.m. Experimental and Therapeutic Research on Snake Venoms Dr David I. Macht Greater Boston Medical Society Beth Israel Hospital auditorium

BOOK REVIEWS

Physical Diagnosis By William Nance Anderson, MD 8°, cloth, 424 pp., with 92 illustrations Philadelphia Lea & Febiger, 1940 \$4.75.

It is interesting that a field like that of physical diagnosis, in which so very little is going on, should continue to produce such an abundance of modern textbooks. There is always someone eager to tell us once again the old familiar story of Williams's tracheal tone, of Gerhardt's sign, of Traube's semilunar space and of Litten's phenomenon, and to give us the newest slant on stoddard tympany.

Most of these books are too big. All that a student of physical diagnosis need know could easily be contained in a pocket manual of less than two hundred pages. If such authors were entirely realistic, they would show the student how to hold his fingers and properly elicit the note of pulmonary resonance, then confide to him the secret that, if one really wants to know whether a patient has pulmonary tuberculosis, the chest is x-rayed.

The author of a manual of physical diagnosis has a few definite obligations to the students who receive their elementary instruction from his text. He should accurately describe the fundamental methods of procedure and should present a few facts in clear and systematic illustration of the results to be obtained through their use. The content of Dr Anderson's book is adequate, and his method of presentation is reasonably good. The grammatical construction, however, leaves a good deal to be desired, and such gross errors as 'Siedlitz' powder, 'Rhefus' tube, 'herz buckle' and 'decubital' artery should not have escaped the proofreader. In all good will it must be said that, although the book should not be condemned, there are half a dozen others on the same subject that are at least its equal. A free use of the editorial blue pencil and the addition of a greater number of illustrations would enhance its appeal.

Psychological and Neurological Definitions and the Unconscious By Samuel Kahn, MD, PhD 8°, cloth, 219 pp. Boston Meador Publishing Company, 1940 \$2.00

This interesting little volume, dedicated to the memory of Sigmund Freud, is a combined psychological dictionary and discussion of the theories of the unconscious and the development of psychoanalysis. It is not exhaustive, only a few of the outstanding psychological theories and conceptions are discussed, but these are preeminently of a psychoanalytic nature. The definitions comprise psychological, psychiatric, psychoanalytic and neurological terms.

The chapters give in turn the history of psychoanalysis, the biography of Freud, the philosophy of the unconscious, its psychoanalytic point of view, and various speculations on unconscious activities. One feature is the author's insistence on a fact that analysts have long emphasized and that has led to the development of training institutes, namely, that a personal or preparatory analysis is necessary before one can successfully practice analytic therapy.

The last chapter of the book comprises an extensive bibliography on psychoanalysis, mental hygiene and educational psychology.

An Index of Treatment. By various authors. Edited by Sir Robert Hutchison, Bart., M.D., LL.D., F.R.C.P., assisted by Reginald Hilton, M.A., M.D., F.R.C.P. Twelfth edition, revised. 8°, cloth, 996 pp., with 148 illustrations. Baltimore: Williams & Wilkins Company, 1940. \$12.00.

This is a standard British reference work. Its popularity may be judged from the fact that the book is now in its twelfth edition since it first appeared in 1907. It had gone through six editions by 1911. The editor, Sir Robert Hutchison, is president of the Royal College of Physicians. There are about seventy-five contributors, all of them British. They include such eminent figures as W. Russell Brain, J. P. Lockhart-Mummery, P. H. Manson-Bahr and Thomas A. Ross. Yet this book has been little used in this country, no recent edition being found, for example, in the Boston Medical Library.

The preface states: "The whole book has again been thoroughly revised and some of the articles entirely rewritten." However, one suspects that revision has been less than complete. For example, although the article on pneumonia does carry one short paragraph on sulfa-pyridine (mentioned only as M.&B. 693), it still includes a long section, headed "To combat toxemia and septicemia," that discusses bleeding, diaphoresis, catharsis and diuresis. The section heading has the following curious footnote: "This section is partly traditional and some of the methods mentioned are probably becoming obsolete." The article on tabes dorsalis still recommends Pyramidon for tabetic pains. In the treatment of tapeworm and roundworm infestation, there is no mention of carbon tetrachloride, tetrachlorethylene or hexylresorcinol.

The book is written, of course, for English use, and many of the proprietary preparations mentioned are limited to that country, as are some of the methods and ways of life discussed. For the most part, however, the text has been brought up to date; the articles are brief and concise, and the book will undoubtedly be of much aid to the general practitioner and student.

Clinical Methods: A guide to the practical study of medicine. By Sir Robert Hutchison, Bart., M.D., LL.D., F.R.C.P., and Donald Hunter, M.D., F.R.C.P. Eleventh edition. 16°, cloth, 622 pp., with 19 color and 8 half-tone plates and 106 figures. New York: Paul B. Hoeber, Inc., 1940. \$5.00.

The eleventh edition of Hutchison and Hunter, the fat, little British equivalent of Seiffert and Mueller, has been reduced to a mere six hundred and twenty-two pages. It is a complete manual of clinical diagnostic procedures, many of them obsolete, from the "examination of vomit" to tables of conversion from imperial weights and measures to "milligrammes" and "centimetres."

The difficulty with imported texts is that no matter how great their time-honored and deserved popularity in the land of their origin, their abundant data do not correspond to American needs. We do not use the Mackenzie-Lewis polygraph, to the description and use of which ten pages are devoted; nor are Gowers's, Haldane's and Oliver's hemoglobinometers, covered in four pages, or Gerrard's hypobromite ureometer, illustrated by a woodcut engraved in 1895, to be found in our hospital laboratories. MacLean's method of estimating sugar in the blood, his urea-concentration test, and the Jenner, Leishman and

Ehrlich tri-acid stains are not in general clinical use in this country. Many other examples might be cited. Any one of the several American house-officers' handbooks that contain information of contemporary value is preferable to even a revised edition of this respected and admirable volume.

Child Care and Training. By Marion L. Faegre and John E. Anderson. Fifth edition, revised. 8°, cloth, 320 pp., with 29 illustrations and 3 tables. Minneapolis: University of Minnesota Press, 1940. \$2.50.

This is one of the best of the home manuals on child care and management—one that can be recommended enthusiastically and without reservation. Its primary aim is to provide a sound and adequate psychological basis for understanding the child, without which all education is indeed futile. And this it does admirably. But the book is by no means restricted to generalities; it answers scores of specific questions about habit formation, learning, family relationships, growing, eating, sleeping, discipline, play, sex education and even the common contagious diseases. Moreover, for the reader who wishes to pursue his inquiries further there are bibliographies at the ends of the several chapters, and there are tables of questions adaptable for classroom use or round-table discussions. One can wish for this book a still wider sphere of usefulness.

Sulfanilamide, Sulfapyridine and Allied Compounds in Infections. By Maurice A. Schnitker, M.D. Edited by Henry A. Christian, A.M., M.D., LL.D., Sc.D. (Hon.), Hon. F.R.C.P. (Can.). 8°, cloth, 72 pp., with 4 illustrations. New York: Oxford University Press, 1940. \$1.50.

The chemotherapy of infections with drugs of the sulfonamide group is a field so new, so vast and so rapidly advancing that it is difficult for the practitioner to assimilate the newer knowledge of this subject and to keep up with its progress.

This small, compact book—reprinted from *Oxford Loose-Leaf Medicine*—will be found tremendously helpful and informative. It reviews the pharmacology, action and methods of administering sulfanilamide and sulfapyridine, the particular infections in which each is or is not effective, the toxic effects and the methods of determining the drugs in the blood, urine and body fluids. The information and directions are so detailed that reference to any other source is unnecessary. The author discusses briefly a few other related compounds, but not recently developed ones, such as sulfathiazole. There is an exhaustive bibliography, and a foreword by Dr. Henry A. Christian.

It Is Your Life: Keep healthy, stay young, live long. By Max M. Rosenberg, M.D. 8°, cloth, 450 pp. New York: The Scholastic Book Press, 1940. \$2.50.

The idea of this book had its origin in the author's occasional practice of distributing to his patients printed folders on the preservation of health and the prevention of disease. The work covers a wide range of subjects and is written in an easy style. Although on the whole the text may serve to teach and guide the average person in his daily mode of living, it should be pointed out that the author frequently presents his material in the spirit of excathedral pronouncement, and that certainly at times he oversteps his experience and discrimination on matters which could be left to those better equipped to pass final judgment.

NUMBER 6

SYMPOSIUM ON SULFANILAMIDE AND ITS DERIVATIVES

SULFANILAMIDE IN THE MANAGEMENT OF ACUTE STREPTOCOCCAL, PARTICULARLY SCARLATINAL, INFECTIONS OF THE UPPER RESPIRATORY TRACT*

CONRAD WESSELHOEFT, M.D.†

BOSTON

IN discussing the use of sulfanilamide in streptococcal infections of the upper respiratory tract, it is essential to keep in mind that certain factors influence the natural course of these infections and the efficacy of the drug, and that such controlled clinical investigations as have been made serve merely as preliminary tests, which gauge the value of the drug only under limited conditions in a complex field. Naturally, these considerations lead to generalities, often of a hypothetical and speculative nature, from which diverse opinions are evolved.

Among these upper respiratory infections of streptococcal origin, scarlet fever offers one suitable avenue of approach because of the vast amount of basic statistical material to work from. This disease in a two-year-old child will give rise to an otitis media in almost 50 per cent of the cases, but the susceptibility of the middle ear in this disease decreases as one grows older, until in adults it occurs in only about 5 per cent. This complication varies not only according to age, but also according to the anatomic peculiarities of the patient, the season of the year, the presence of mixed infections,¹ the strain of hemolytic streptococcus obtained from nose and throat cultures² and the various little-known influences connected with the patient's environment. Similar factors pertain to the incidence of the other complications of this disease.

It must be clearly understood that these scarlet-fever strains can produce pharyngitis, tonsillitis, lymphadenitis and all the other complications without producing a rash, provided that the patient

can neutralize the toxin. Furthermore, other strains of streptococci—not of the scarlet-fever order—can give rise to a similar pharyngitis and tonsillitis with fever in all grades of severity, and to the complications that accompany and follow scarlet fever.

In their superficial growth, these various streptococci may call forth a thin layer of fibrin and may also cause marked localized edema. But their invasive power actually governs not only the severity of the local symptoms in and about the throat, but also the incidence of accompanying and subsequent complications. They can induce a mucopurulent discharge from the mucous membrane, especially in the middle ear, the mastoid cells, the nose and its accessory sinuses. In all these positions there is a constant effort of the resisting forces to protect the underlying structure from the streptococci. However, the bacteria may penetrate still deeper and may seriously invade the lymphatics or bone itself, and thus may reach the blood or the meninges.

How does sulfanilamide influence these upper respiratory conditions? Various factors affect its ability to inhibit the growth of hemolytic streptococci. As a class, these bacteria are among the most susceptible to this drug. Nevertheless, certain strains are more susceptible than others.^{3,4} Furthermore, one is not always dealing with a pure strain. Frequently there are mixed infections in which one strain may supersede another in its preponderance of growth. The tissue involved, the tissue reaction invoked by the infection, and the depth of invasion are of the utmost importance. Indeed, the efforts of the natural resisting forces to wall off and localize the infection may also act to prevent sulfanilamide from getting at the streptococci flourishing within the wall. But it is not only in abscess formation that this walling-off takes place, because fibrin thrown

*This and the following four papers were presented at a symposium at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1940.

†From the Haynes Memorial Hospital, Massachusetts Memorial Hospitals, and the Department of Pediatrics, Harvard Medical School.

‡Clinical professor of communicable diseases, Harvard School of Public Health, associate professor of theory and practice, Boston University School of Medicine, physician in-chief, Haynes Memorial Hospital, Massachusetts Memorial Hospitals.

into and on the surface of the mucous membrane of the upper respiratory tract and the relatively impotent superficial phagocytic cells may protect streptococci flourishing near the surface and in the semifluid on the surface. Especially is this true in certain forms of purulent rhinitis. Thus one is confronted with different problems brought about by the elaboration of the toxin on the one hand, and pyogenic properties on the other.

Ordinarily, the initial invasion of the scarlet-fever infection is a superficial one. The rash is a remote effect of the circulating toxin on the skin capillaries, whereas in erysipelas the skin lesion is the direct result of the streptococci within the tissue fluids in the deeper layers of the skin itself. Consequently, sulfanilamide, or the form in which it operates, encounters more difficulty in reaching the superficial lesions of the upper respiratory tract in scarlet fever than it does in affecting the deep skin lesions of erysipelas. Therefore, one should not expect, nor does one obtain, parallel results in the two diseases from the administration of this drug.

Scarlet fever offers an excellent opportunity to investigate the action of sulfanilamide. Given as a routine by mouth throughout the febrile stage in the accepted dosage,* this drug has failed to benefit in any way the eruptive stage in eight clinical studies,⁵⁻¹² comprising a total of 1239 cases tested against 1220 controls. One of these studies was conducted at the Haynes Memorial Hospital, the results of which conformed with the others in this respect: the fever was neither lowered nor shortened, nor was any improvement noted in the rash or sore throat that could be attributed to the drug, as determined by a comparison with the control series.

Tonsillitis is a usual manifestation of the initial stage of scarlet fever, and in our series it showed no apparent improvement as the result of the usual dosage of the drug. Why, then, should the non-scarlatinal forms of pharyngitis and tonsillitis be expected to yield to this or to smaller doses? A controlled study failed to show that they do.¹³ Both types of tonsillar disease represent invasion, and the only difference lies in the local toxic effects in scarlet fever.

However, if scarlet-fever antitoxin or convalescent serum is administered within the first twenty-four hours, one usually obtains a dramatic drop in the fever, a blanching of the rash and a distinct improvement in the inflamed throat. Here the improvement in the condition of the throat is due to neutralization of the erythrogenic toxin and indirectly to a checking of the bacterial invasion. Thus one can control the toxic stage by the

early use of antisera, which will lower the incidence of complications during the first week to an appreciable degree. But scarlet-fever antisera exert no more effect on the pyogenic complications, once they have become established, than sulfanilamide exerts on the initial toxic stage.

The next question is whether sulfanilamide can prevent these pyogenic complications. In four of these clinical tests the drug was continued only during the febrile stage. The combined results of the tests^{5-7, 9} (474 treated cases, 587 controls) showed no diminution in the incidence of complications. Furthermore, in England,^{9, 10} a combination of the drug with scarlet-fever antitoxin was used in 317 cases and controlled by 329 cases in similar age groups treated with antitoxin alone. Again no diminution of the complications occurred as a result of the sulfanilamide, in spite of this additional antibody supply. On the other hand, Benn¹¹ and Silverman¹² showed a moderate reduction in the pyogenic complications among their drug-treated cases. All these clinical observations are of necessity unsatisfactory and incomplete, since the results always suggest some other approach in the manner of administering the drug, if not some newer allied preparation.

In a series of 350 cases reported by Thenebe and his associates¹⁴ at Hartford,—in which the usual dosage was given on the first day, reduced over a period of the next three days, and then maintained at half the original dose for another four days,—a low percentage of complications occurred as compared with that in previous years, but a very high percentage of toxic effects from the drug was recorded.

In another series—that of Sako and his associates⁸ in Minneapolis—the drug was used without antitoxin and was continued on an average of twelve days. Here a very marked diminution in the incidence of complications was reported in the drug-treated cases. The authors remark that “the best results were obtained when sulfanilamide was continued during the entire convalescent period,” but they fail to state how many were so treated and what their ages were.

All the complications of scarlet fever may occur at any time during the course of the disease. Schick,¹⁵ years ago, drew attention to the “second danger period,” extending into the third or the fourth week. The continued use of sulfanilamide over a three or four weeks’ period brings up the question of the dangers from its use, especially in the home. Cases so treated would certainly require closer supervision, with frequent blood counts, and thus add to the cost of medical care. This, of course, would be well worth while if complications could be avoided or reduced to the minimum obtained in the Minneapolis series.

*Sixty to 90 gr. daily by mouth was used for full-grown patients, with proportional reductions according to weight down to 20 to 40 gr. daily.

From a practical standpoint it means hospitalization of all cases of scarlet fever, a reversal of the present tendency toward isolation in the home.

Jewell¹⁶ has recently reported on the use of small doses of sulfanilamide (2 to 5 gr thrice daily) as a prophylactic for scarlet fever. Similar spectacular results were offered sixty years ago in favor of belladonna in this same capacity. The references on the latter subject fill two columns of the *Surgeon General's Catalogue*. The control method of investigation will eventually give the true answer to the prophylactic value of sulfanilamide in this disease, as it did for belladonna.

In other contagious diseases not of streptococcal origin, hemolytic streptococci are, nevertheless, frequently the cause of complications. Thompson and Greenfield¹⁷ used sulfanilamide in measles and whooping cough in the usual dosage, followed by a maintenance dose in carefully controlled age groups. The drug showed no effect whatever on the eruptive phase of measles or on the paroxysmal manifestations of pertussis, but the incidence of bronchopneumonia was reduced in both diseases in the drug-treated series. Furthermore, there was a material reduction in the incidence of otitis media in the 400 cases of measles that were given sulfanilamide, comparable with the results obtained by Siko and his associates in scarlet fever with a maintenance dosage. Here, again, one must weigh the prophylactic value of this continued method with the actual days of illness caused by the drug—by no means a minor item, even in children, in whom it is relatively well tolerated.

Sulfanilamide is exceedingly valuable in reducing the mortality that follows the onset of serious complications. In scarlet fever the majority of the deaths today are due to the end results of pyogenic infections, particularly of the mastoid cells, in which the blood stream or the meninges become invaded. In these two serious complications, bacteremia and meningitis, the death rate has been so markedly reduced as to make me enthusiastic.

As to the use of sulfanilamide in purulent rhinitis, sinusitis and suppurative otitis media, our experience at the Haynes Memorial Hospital is very conflicting. Some cases with and without evidence of septic toxemia appear to have responded, whereas in others the results are disappointing. This experience in scarlet fever corresponds to the conflicting reports in the literature in these same conditions not of scarlatinal origin. Evidence on this point must be carefully sifted before anything beyond impressions can be given.

In 54 cases of suppurative otitis media in the course of scarlet fever we have given sulfanilamide

from the onset of the aural discharge in 14 and later in 40. In this preliminary report I can say only that the duration of the discharge and the incidence of mastoid infection requiring surgical intervention have not been reduced below the average. One thing that we have learned is that a mastoiditis may be subdued so far as the purulent aural discharge is concerned, yet bone destruction continues, and precious time has been wasted.¹⁸ Furthermore, the white cell count and differential count can be distorted by the drug, likewise the x-ray evidence, as pointed out by Law,¹⁹ thus making it more difficult to interpret the true condition of affairs in the mastoid cells.

Different strains of hemolytic streptococci appear to have various predilections for their original attack. For example, it is fairly unusual for the scarlatinal strains to attack the larynx; yet other strains of hemolytic streptococci can bring about an epidemic of croup. Here one may be confronted by a problem in the use of sulfanilamide. I refer to obstructive laryngitis. At the Haynes Memorial Hospital we have seen 3 cases of severe obstructive streptococcal laryngitis which, before admission, were given sulfanilamide to the point of cyanosis, without improvement. Nor were these due to the viridans type of streptococcus, which is known to be resistant to this drug. Cyanosis and signs of fatigue constitute indications for laryngoscopic examination, suction and, if necessary, intubation, or, in extreme danger, for a prompt indirect intubation. Of course, the cyanosis of sulfanilamide would never alone bring one to this step, but in the presence of increasing obstruction it can handicap one's judgment.

Two one-year-old infants with streptococcal laryngitis were recently admitted to the Haynes Memorial Hospital, both with marked funnel-like recessions of the sternum with each inspiration. They did not develop excessive fatigue or cyanosis, and recovered with moist air inhalations alone. Sulfanilamide was not used.

Intubation is a much more serious step here than in diphtheria, owing to the danger of ulceration if the tube is left in place more than forty-eight hours. Intubation, therefore, with a streptococcal infection is a temporary procedure to afford sufficient sleep and rest and a chance to combat dehydration before a tracheotomy, and to supply free air passage during the tracheotomy, which is done under local anesthesia. In spite of advances in the technique and aftercare of tracheotomy, the dangers of bronchopneumonia and tracheal encrustations continue to make this operation a great risk. Any drug that induces cyanosis in the presence of laryngeal obstruction might mislead one into unnecessary operative interference. Sulfathiazole

zole, which does not appear to have this drawback, is now under investigation.

In spite of appearing inconsistent because of inferences to be drawn from our experience in scarlet fever and obstructive laryngitis, I am of the opinion that drastic chemotherapy is indicated in any desperate, fulminating, highly toxic infection of the faucial space and trachea suggestive of streptococcal infection before any culture reports are obtained; and if the cultures are positive for hemolytic streptococcus, I should add immunotransfusion. But I am opposed to its indiscriminate use in the minor upper respiratory infections, except those under investigative control.

In the management of the streptococcal infections of the upper respiratory tract one should be aware of the factors that govern the natural course of the disease and those that interfere with the ability of the drug to get at the bacteria, the variations in their susceptibility and the limits, as well as the dangers, of its use. Nor should one neglect all those useful measures that afford relief, comfort and the saving of life. Improvements in chemotherapy may yet fulfill our hopes in the treatment of these upper respiratory streptococcal infections, but much investigation lies ahead. At present the outstanding value of sulfanilamide appears to be in those sequelae of these infections in which the streptococci have penetrated into the blood stream, the meninges or the lungs.

DISCUSSION

DR. GORDON BERRY, Worcester: The subject of chemotherapy is broad and complex. I know you join with me in wishing that the time would permit a wider development of the theme by so authoritative a speaker as Dr. Wesselhoef.

It should be remembered that in streptococcal infections, a specialized type of membrane is being considered and that each infection invades this membrane in the same way. Through the agencies of local edema, the deposit of a fibrin layer on and in the superficial tissues and the local increase of phagocytic leukocytes, Nature is delaying, or preventing the entry and spread of the bacteria, is trying to wall off the process and isolate it. I cannot speak authoritatively about the chemical or pathologic changes that occur, but I can fittingly emphasize the point made here, namely, that sulfanilamide is blood borne, and that the very barriers Nature establishes in its effort to wall off the process automatically inhibit the drug from reaching the infection. Further, if there is central necrosis and pus formation, the pus is beyond the reach of this drug. Here if Nature cannot cure, only mechanical drainage will serve.

Although antisera markedly inhibit the initial attacks of streptococcal infections, but not the later complications, sulfanilamide, even if started early and energetically and continued in gradually diminishing doses, does not lessen the initial attack, but does lessen the pyogenic complications. Some would question this, and further research is necessary to settle the point.

I shall now discuss ear complications, which are of particular interest to me as an otolaryngologist. In a series of 54 cases of acute suppurative otitis media, the administration of sulfanilamide did not reduce the duration of the discharge or the incidence of mastoiditis requiring surgical intervention. These negative findings are supported by many of my confreres, but are contrary to the reports of those enthusiasts who claim a startling abatement in ear infections from prompt chemotherapy in all cases.

Let me introduce two contrasting reports. The first, in favor of chemotherapy, is through the courtesy of Dr. Mary S. Holmes, the superintendent at Belmont Hospital, where Worcester's acute contagious cases are handled. The material was assembled by her assistant, Dr. Florence H. Knowlton. This hospital makes a routine practice of administering sulfanilamide (1 gr. per pound of body weight) in all scarlet-fever cases. To protect against sensitivity, the drug is continued for only five days unless the severity of the case or secondary complications urge a continuance. What are the results? The scarlet-fever death rate for the preceding ten years was 1.5 per cent. For the two years of sulfanilamide therapy, 840 cases resulted in 5 deaths, a rate of 0.6 per cent. The incidence of acute otitis media for all ages was 6.8 per cent in an untreated series of 1018 cases and 2.5 per cent in a treated series of 827 cases. These figures show a gain of about two and a half times. Mastoidectomy, not infrequent in the untreated series, was a rarity in the treated. In 1935 and 1936 the average hospital stay for scarlet fever with otitis media was 47 days. In 1938, when the drug was used as a routine, the average stay was reduced by a half, to 23 days. The fever and the rash disappeared promptly in most of the treated cases. Antiserum was used in a little less than one quarter of the cases in both series. Dr. Holmes credits these results to the sulfanilamide therapy, and also to the isolation of each case in a separate room, thus avoiding cross infections. In over 1000 cases administered sulfanilamide in this hospital, no serious toxic complications were caused by the drug.

The second report reflects the more conservative attitude of most otologists. Dr Edmund P. Fowler, Jr.,* has listed the types of organisms found in cultures from aural discharges at the Columbia Presbyterian Medical Center in New York during the last seven years. Such cultures should indicate the primary offending organism. But it must be borne in mind that secondary infections early enter from the nasopharynx or from the skin of the external auditory canal, and that the resulting mixed infection complicates therapy. Sulfanilamide may be helping the streptococcal infection while a complicating staphylococcus is causing serious secondary trouble. The total number of cases in this New York series was 2755. Of these over 35 per cent showed staphylococcus, and more than 15 per cent, other organisms, thus over 50 per cent were not susceptible to any known specific chemotherapy. (Sulfapyridine and sulfathiazole are offered for staphylococcal infections, but they are not yet considered specific remedies.) About 30 per cent of this series showed hemolytic streptococci, for which we have sulfanilamide, and about 15 per cent were due to pneumococci for which we have sulfapyridine. A second study showed the duration. In a series of 455 cases of acute suppurative otitis media that did not receive chemotherapy, and a hospital is likely to see the worst forms,—the total duration of the ear discharge in all types of infection was less than one week in 68 cases, less than two weeks in 209, and less than three weeks in 269. Of the 264 cases with pneumococcal and streptococcal infections, including the severe complications, three quarters of the patients got well within three weeks without chemotherapy. Dr Fowler reasons that acute otitis media is usually a self-limited disease and that too many cures are being attributed to chemotherapy. He thinks a fair estimate of cures by such means, as against former measures, would place the gain at less than 5 per cent. His figures show that less than half the cases of otitis media lend themselves to chemotherapy and that three quarters of this possible half recover about as promptly without the use of the specific drug. He concludes that perhaps one eighth of all cases of acute otitis media need chemotherapy.

In considering infectious processes in this region, one should bear in mind that all these cavities are bony, epithelial lined air chambers connected with the central airway. The middle ear and mastoid may be thought of as a modified paranasal sinus. An acute nasal cold always involves to a degree the easily accessible ethmoid cells. If it extends through the eustachian tube, the infection involves the mastoid cell membrane almost as soon as that of the tympanum. We shall clarify our reasoning if we accept this early involvement of these contiguous cavities. Treatment may employ belladonna as of old, or the sulfanilamide of today, but locally we must seek and secure drainage of these adjacent cavities. Dr Wesselhoef explains why the sulfanilamide will not reach them. To drain the paranasal sinuses, we shrink the turbinates and ostia; for the middle ear, we shrink the eustachian tube. If the ear fails to gain, then we must seek surgical drainage through the eardrum or later through the mastoid cortex.

Up to this point most otologists rarely use chemotherapy. I cannot see the wisdom or logic in using the drug in mild self-limited nasal and aural infections or in a localized suppurative mastoiditis. Why submit a patient, who probably will get well promptly, to such a heavy broadside, with its known dangers? And the drug masks the symptoms, as Dr Wesselhoef has pointed out. The

fever may drop, the pain and discharge may cease, the drum membrane may heal and the hearing may return, and still one may be forced to operate, finding an active pocket of pus in the mastoid. I insist, therefore, on surgical drainage when I think it called for. I have almost invariably regretted an undue reliance on chemotherapy. There are two exceptions to this initial postponement of sulfanilamide. One is an acute fulminating streptococcal infection, regardless of its locality, here the infection is breaking through Nature's barriers, and one must call on the reserves at once. The second exception is an acute streptococcal mastoiditis, for which a free myringotomy has been done and which is hanging in the balance. A short intensive course of sulfanilamide therapy, gradually withdrawn, may favorably turn the scale. But its masking effect, in addition to its hazards, must be carefully borne in mind.

One possibility not yet finally evaluated is its local use. Sulfanilamide in powder form can be applied directly to infected surface tissues, or Neoprontysil in solution can be injected into cavities. Some claim good results, others are not certain.

Except for this possible local use and until the experts recommend smaller and safer doses, one should tend to reserve this modern offensive weapon for the major battle. At any point when the infection looks as though it might seriously reach beyond Nature's normal barriers, then call on this reserve, unstintingly. Dr Fowler accepts a week to ten days of the infection as an arbitrary limit if the infection is not under control by then, use the drug. This is a helpful rule. Some of us prefer to consider each case individually and call on this help promptly when we think that convalescence is not progressing well. Please note the time limit seven to ten days. But experts in chemotherapy say that the hazards from drug sensitivity tend to develop from the seventh to the tenth day. Many withdraw the drug then in order to avoid these hazards. This is just the time the otologist begins to need the drug for the severe complications that may develop. The obvious question is, Why use up this valuable aid when one does not need it, and withdraw it at the time when one may sorely need it? The otologist concludes reserve the drug for these later complications.

I cannot here go into a detailed consideration of the dangers of chemotherapy. We have all experienced them. Although sensitivity develops more frequently from the seventh to the tenth day, it may develop more promptly. And although we are urged to force the drug in massive doses right at the start, small doses as well as large can bring on these unfortunate reactions. The doctor must therefore decide first whether with a little waiting the patient can get the best of the infection without the drug and secondly, whether, if he uses the drug, the expected gain is greater than the hazard. And bear in mind that a good many patients whose cures have been attributed to chemotherapy would have recovered anyway.

At the last meeting of the New England Otological and Laryngological Society, Dr Champ Lyons gave a masterly dissertation on chemotherapy, urging its prompt and energetic use. If the proper and specific drug is available for an acute middle ear infection, he urges its use right at the start, in heavy doses and with the patient hospitalized, always. If the drug is doing what it should do the fever will be down and the ear dry within forty-eight hours. But such an intelligent and drastic effort predicates expert laboratory checking not only of the drug content in the blood and its effect on the red and white blood cells, but of the immune bodies present. If these immune bodies are abundant the drug is less need

*Fowler, E. P., Jr. Otitis media and its extensions. *J. N. Y. Acad. Med.* 16:24-37, 1940.

ed; if they are lacking, he recommends not only chemotherapy but the considered use of antiserums. In such expert hands, chemotherapy becomes an exact science, and its reactions and hazards are known and understood. As yet the average hospital and laboratory enjoys neither the financial resources nor the technical skill for these elaborate procedures in routine practice. And very few patients can afford to call a mild earache a major hospital disease, even though serious complications may be brewing. In the meantime it is to men like Dr. Wesselhoef and Dr. Lyons that we gratefully look for safe and wise leadership in this remarkable field of chemotherapy.

This brings me to Dr. Wesselhoef's final point: the use of sulfanilamide in streptococcal extensions from the ear and mastoid, or from the nose and paranasal sinuses, to the meninges or to the blood stream. Here otologists are in complete accord: begin the therapy at the first suspicion of trouble. The patient is in the hospital and has been under observation. The culture report has been made, the blood and kidney condition is known. Now use the drug promptly and in massive doses. Keep the fluid intake down to hasten the blood saturation—8 mg. per 100 cc. is usually enough, but do not hesitate to go to 12 mg. or even higher. To the otologist who formerly labored

frantically but without avail on his meningitis and sinus-thrombosis cases, the results are little short of miraculous. The case is desperate, surely, but the patient now has a good chance of recovery, provided of course that any necessary surgical drainage has first been secured. Here the drug hazard does not weigh in the balance against the great gain to be secured.

The one caution that experience indicates is not to withdraw the drug too soon. I have operated on the mastoid, controlled the meningitis, withdrawn chemotherapy and sent the patient home apparently well, only to have him hurried back to the hospital in a few days with a second attack of frank meningitis. Fortunately, more sulfanilamide is usually successful in bringing about a lasting cure.

One thing we now hope for is a drug that can be used with safety and in small prophylactic doses. We need therapy that can be administered at the office or at the home, and that will control the infection in its initial stages. Until chemical research corrects the known faults and makes laboratory control simpler, otolaryngologists will tend to hold this most valuable agency as a reserve against serious secondary complications. In the meantime, discussions like these will clarify the existing confusion and will help to guide our procedures.

THE TREATMENT OF PUERPERAL SEPSIS*

JOSEPH P. COHEN, M.D.†

BOSTON

THE advance of knowledge in chemotherapy has stimulated interest in the treatment of puerperal sepsis. Despite this, however, it should be kept constantly in mind that the keynote of emphasis should remain the prevention of the disease. The vaginal tract rarely harbors organisms that are productive of serious infections. These organisms are introduced extragenitally. According to Chandler¹ the incidence of Group A strains of the beta-hemolytic streptococcus in the vagina before delivery is 0.25 per cent, yet in patients with severe puerperal infections almost 100 per cent of the strains isolated bacteriologically are in Group A. The treatment of puerperal sepsis, therefore, begins with preventive measures in the prenatal period, continues with rigid adherence to aseptic principles throughout the intra-partum phase and is not concluded until the post-partum period is completed.

Ante partum, patients should be admonished against intravaginal manipulation, particularly in the last month of pregnancy. They should be instructed not to take douches; coitus should be interdicted.

To protect the patient during delivery, the delivery room should not be used for surgical prac-

tice, masks should be worn by all attendants, and patients harboring intercurrent infections should be delivered under conditions that ensure isolation. Proper sterilization of the instruments and gloves is fundamental. Persons who are known to have respiratory infections should be kept out of the delivery room, and if the patient herself has a respiratory infection, every precaution should be taken to avoid autoinfection. Patients must be shaved, and scrupulous aseptic technic should be practiced during delivery. Vaginal examinations should be reduced to a minimum during labor, even though they may be conducted with a rigid technic. As a matter of fact, the progress of labor is readily followed under most conditions by rectal examinations. Prior to delivery the patient should be draped with sterile sheets after preparation of the skin and vulva with suitable antiseptics, and the operator scrubbed as if for the most important surgical adventure, for so the simplest obstetric case may turn out to be.

Post partum, all patients are isolated who have a temperature of 101°F. for a period of a few days, particularly when accompanied by chills, elevated pulse, headache, anorexia, and nausea and vomiting. Prompt isolation will reduce the incidence of epidemics. One should rule out engorged breasts, gastrointestinal disorders and known contagious diseases that do not require isolation. Patients who are to be isolated are

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1940.

†Instructor in obstetrics, Harvard Medical School; surgeon-in-chief for gynecology and obstetrics, Boston City Hospital.

placed in a separate ward or building under the charge of nurses who have no responsibilities with other patients. Wards are frequently scoured, fresh linen is given daily to each patient, bedpans are sterilized before they are used, and nurses are taught a rigid technic in the use of antiseptics. Nurses with local or pulmonary infections should be removed from duty. These details of prophylactic care are essential to reduce the spread of puerperal infections and are of prime importance in the treatment and eradication of the disease.

Since devitalized tissues play an important role in creating conditions favorable to the growth of organisms,² the attendant must avoid traumatization; his judgment must be good, his skill ingenious. This means early selection of cases for cesarean section, preferably before rupture of the membranes and within twelve hours of the onset of labor. One should adhere to the precepts of delivering patients vaginally only at full dilatation, and when the delivery is instrumental, of employing gentle traction after an intelligent application of forceps. Except in cases of retained placenta or post-partum hemorrhage, the completion of the third stage of labor without intrauterine exploration is vital.

To give intelligent care to an obstetric patient who is septic, that patient should be properly evaluated not only from the evidence furnished by signs and symptoms of the disease but also by bacteriologic and hematologic studies. To clarify diagnosis, to aid in prognosis and to render intelligent therapy one should know what organism or organisms one is dealing with and whether the infection is localized or in the blood stream; therefore, cultures should be taken from the cervix and the uterus, and blood cultures should be obtained early, and repeated if negative. At the same time blood studies are conducted to determine the red-cell and white-cell counts. The streptococcus, staphylococcus, pneumococcus, colon bacillus and gonococcus are the commonest infecting organisms of the genital tract of the parturient woman. The infections that most seriously jeopardize the patient's life are for the most part confined to beta-hemolytic streptococcus. Almost all human strains of the beta category fall into Group A. Other streptococci produce only partial hemolysis, and certain anaerobic types have the vagina as a normal habitat and are not pathogenic.

Since most of the puerperal infections tend to remain localized in the cervix, uterus or parametrium, the uterus should be kept contracted with oxytocics used orally or parenterally. Ergot and pituitary extract are given early post partum and

are continued for the first three to five days. Intrauterine procedures such as douches or curettage are contraindicated^{2, 3}; they disseminate infection and may prove fatal.

In generalized blood infections, the hemolytic streptococcus acts by invasion and growth in the host and by the elaboration of toxins. The body mechanism employs phagocytosis and intracellular digestion to oppose this growth. The bacteria may develop a protective mechanism—a capsule—that hinders the phagocytic process. Since sulfanilamide, sulfapyridine and sulfathiazole have been found to be bacteriostatic in vitro and in vivo, they have become utilizable in the production of bacteriostasis.

But this is not always enough. It was found that this phagocytic action might be increased by the presence in the blood of a specific antibody that is antibacterial in nature and sensitizes the organism. This specific antibody, termed opsonin, can be evaluated in the laboratory by blood examination. Therefore, in those patients who possess a low opsonic index, the opsonin may be increased by the transfusion of blood from an immune donor or one found to possess a relatively high antibody content. Treatment by means of sulfanilamide in combination with immune transfusions seems ideal. Colebrook and Purdie⁴ showed reduction in the total case fatality rate in puerperal sepsis of 62 per cent, whereas the fatality rate in bacteremic cases fell from 75 per cent to 27 per cent after the use of chemotherapy.

To confirm the bacteriologic diagnosis, blood cultures should be taken before the administration of sulfanilamide. Blood cultures taken after therapy has been started are likely to be negative. If so, and if the history and intra-partum experiences indicate that the patient is potentially infected, it is justifiable to employ chemotherapy prophylactically.

Sulfanilamide or one of its derivatives must not be employed without an understanding of the toxic properties and must be administered under strict supervision, so that the drug may be stopped when ill effects become obvious. Long, Bliss and Feinstone⁵ noted toxic signs in a series of 307 cases and were impressed with their relative importance. They have listed fever, jaundice, acute hemolytic anemia and agranulocytosis as sufficiently serious to abandon the use of sulfanilamide. At the Boston City Hospital we have found nausea, vomiting and leukopenia common. Cyanosis, although at first a cause for concern, was found later to be no contraindication to the continuance of the sulfanilamide. The occurrence of psychic disturbances has been annoying and severe enough to make it wise to omit the drug

or reduce its dosage. Since sulfanilamide is rapidly excreted by the kidneys, the increased ingestion of water serves to speed up the neutralization and elimination of the drug. Occasionally, when the drug has to be omitted because of its toxicity, it may be resumed after the lapse of a few days, but in smaller doses. It has been our practice to combat the possibility of acidosis by the administration of equal doses of bicarbonate of soda.

Blood observations should be made twice a week to ascertain and maintain the concentration of the drug at a level of 8 to 10 mg. per 100 cc. of blood. This is extremely important to obtain the maximum beneficial effect from the sulfanilamide and at the same time to reduce both the severity and the incidence of toxemia. To maintain a high blood concentration of sulfanilamide it is possible that fluids may have to be reduced so that the daily urinary output is brought to just above 1000 cc. To guard against the development of agranulocytic angina or acute hemolytic anemia, blood studies are made every other day, including red-cell and white-cell counts and hemoglobin determinations. Blood smears should be examined to observe the type of cells.

Although the accepted procedure is to give an initial dose of 5 gr. of sulfanilamide per 10 pounds of body weight, at the Boston City Hospital we have given no more than 40 gr. as the original dose. After that we have given 15 gr. every four hours. Thus most of the patients have received 90 gr. a day, although occasionally they have received 120 and infrequently 180. Blood-level readings should serve as the guide. This was not done routinely.

Although transfusions with the blood of an immune donor are of known and often dramatic benefit to the patient, the transfusions on the maternity wards at the Boston City Hospital were from donors who were merely found to be compatible. As such, the transfusions were used with indifferent success in some very severe cases, whereas in others the results were surprisingly effective. From 250 to 500 cc. of blood was employed at a time. One or two transfusions were usually given, but occasionally six or seven at three-day intervals.

Recently sulfapyridine has been employed on the maternity wards. In vitro sulfapyridine is said to be bacteriostatic in considerably higher dilutions than sulfanilamide. Sulfapyridine, although more rapidly absorbed than sulfanilamide, is less rapidly excreted. We administer 15 gr. every four hours until signs and symptoms subside. However, recent studies by Brown, Thornton and

Wilson⁶ have shown that sulfapyridine is more toxic than sulfanilamide. They have noted oliguria, hematuria and costovertebral pain twice as frequently with the former as with the latter. We have not observed these reactions. Nearly all their cases dealt with pulmonary infections.

In the three-year period from 1937 through 1939 9691 cases were delivered at the Boston City Hospital. There were 49 septic cases, 25 of which were delivered normally; 4 were fatal. Five cases had blood cultures positive for hemolytic streptococcus.

Sulfanilamide was employed in the form of Prontylin in 36 cases. Eleven of these cases had, in addition to sulfanilamide, transfusions of citrated whole blood; usually 500 cc. of blood was given. Five of these 11 cases showed a sharp drop in the fever within forty-eight hours.

Of the 4 fatal cases, 1 was given sulfanilamide for twelve days, that is, from the seventh to the nineteenth day post partum, with sulfapyridine for an additional two days. There was no obvious beneficial effect from the drug. However, only 40 to 80 gr. of sulfanilamide was used daily. The patient died in six weeks of subacute bacterial endocarditis. Hemolytic streptococci were recovered from the blood. The patient was delivered normally. She was not transfused. The levels of sulfanilamide concentration in the blood were not determined.

The second fatal case was delivered by low forceps. The patient developed thrombophlebitis and began running a fever on the eighth postpartum day. On the ninth day she was started on Prontylin and given 60 to 90 gr. a day for seven days. She died on the nineteenth day. The diagnosis of septicemia on the record was not confirmed by blood culture.

The third case, following a normal delivery, ran a temperature of 100 to 100.5°F. for five days, with a subsequent rise to 104. Blood cultures were reported negative. She was given Prontylin, 90 to 120 gr. a day, from the eighth to the tenth day, then 60 gr. daily until the twenty-sixth day, when she died. Nine transfusions of 400 to 450 cc. of blood were given.

The last case was a normal delivery of a premature fetus. The patient had pyelitis before delivery. There was a history of nephrectomy for stone two years previously. The temperature swung from 101 to 105.2°F. A hemolytic streptococcus was recovered from the blood. The patient was given 500 cc. of blood on the thirteenth, fourteenth and sixteenth days and Prontylin, 60 to 120 gr. a day, for ten days. She died on the seventeenth day.

SUMMARY

It is apparent that although sulfanilamide is a valuable addition to our armamentarium in the treatment of puerperal sepsis, it must not be relied on completely. Deaths from these infections continue to occur. The fact that 25 of the 49 septic cases were delivered normally shows that instrumentation per se is not so heavily responsible as is believed and that infection may arise under the simplest conditions at delivery. Transfusions, although known immune donors were not used, are supportive and should be carried out in severely septic cases. Transfusion with the blood of an immune donor has been shown to be of immense value. Despite the evidence of

all known bacteria in the urine, the patient should be continued on prophylaxis for a period of infection.

Which Specific Drug

THE TREATMENT OF URINARY-TRACT INFECTIONS BY SPECIFIC THERAPY

A Clinical Study

E. GRANVILLE CRANFELD, M.D.

BOSTON

THE treatment of urinary-tract infections has recently passed from the stage of administration of a group of comparatively harmless and, for the most part, inefficient drugs, to the use of a group of potent but potentially harmful chemicals.

The term "specific," when applied to these antiseptics, is not easily defined. It certainly does not suggest that the drugs are not suitable for treatment of other than urinary-tract infections. The implication that there is a certain drug that should be administered in, for example, colon-bacillus infections of the kidneys and bladder, to the exclusion of all others, is not in accordance with clinical facts. Perhaps we mean that specific drugs are potent. Without question some of the chemicals are potent. Some of them are able to kill bacteria that are concerned in urinary-tract infections. In this respect they approximate the use of the term specific drugs. It is also abundant examples of failure to cure urinary-tract infections even after serial administration of one, and then another, of these potent drugs. Let us then consider specific urinary-tract drugs to be more potent drugs than those to which we have been accustomed, with sharp difference.

of the urinary tract. It is

degrees of stasis in the urinary tract. It is the degree of stasis in the urinary tract that are not of sufficient importance for treatment. For the bladder, the degree of stasis in the urinary tract probably represents such smaller amounts of stasis in the urinary tract as to interfere with treatment in the pelvis and ureters.

Instant drainage offer little chance for cure so long as the drain is not sufficient. This is particularly applicable to the treatment of the bladder and its surgical treatment. The degree of the drainage does not prevent the use of sulfanilamide from taking place, but does prevent the production of sterile urine.

The treatment of the bladder and ureters involve the urinary tract. This produces abnormal drainage of the urinary channels and with the cure of urinary-

*Presented at the annual meeting of the Massachusetts Medical Society, May 22, 1940.

†Chief of the Department of Urology, Beth Israel Hospital, Boston Lying-in Hospital.

ACUTE INFECTION OF THE URINARY TRACT

Acute infections of the urinary tract show a marked tendency toward involvement of the whole tract, including the prostate in men, when the extent of the involvement is determined by cystoscopic studies rather than by symptomatology. Acute infection of the kidney is pyelonephritis when fever is present.

The acutely infected patient presents not only the question of how best to render the urinary tract sterile, but also the problem of clearing pus from the kidney and of controlling the toxic effects of the infection on the patient, which are manifested in nausea, vomiting, anorexia, dehydration and, if sufficiently long continued, anemia. The severity and duration of the chronic stage of infection often depend on the management of the acute stage of the disease.

I now make use of forced fluids, by whatever means, and alkalinization of the patient's urine as the first stage of treatment. When this has been accomplished for from twelve to twenty-four hours, even though the fever continues, the patient can maintain an intake of fluid at from 3500 to 5000 cc. and can manage a supporting diet adequate to prevent the development of anemia. Antiseptics can then be administered and will be tolerated.

I prefer to use sulfanilamide drugs rather than mandelic acid in treating the acute stage of urinary infections. The preliminary treatment already advocated is aimed at the control of acidosis, and any form of acidification therapy bids for a return to that condition. Dosages of sulfanilamide need not be so large as those commonly given for some other diseases. Forty grains a day, in divided doses over a period of six to seven days, is usually adequate. The blood level produced by sulfanilamide may reach only 2.5 to 6.0 mg. per 100 cc. Sixty grains daily has been required for a few cases. The change to higher dosage will be indicated by the third or fourth day, if it is noted that adequate progress is not being made. On the whole, a patient who is being benefited by the drug will demonstrate a fair degree of improvement by the third or fourth day of treatment. If some signs of clearing of the urine are not apparent, or if it appears to clear and then clouds again during treatment, sterilization of the urine probably cannot be accomplished at this time. Return of temperature to normal will have been accomplished in most cases even though a clearing of the urine has not been obtained. If the patient is alkalinized before therapy is begun, cases of intolerance to the drug will be less common. The prostatitis that frequently accompanies

urinary-tract infection is less likely than the urinary-tract infection to be cured by sulfanilamide therapy, and may persist and give rise to recurrent infection at some remote period. One will do well to test for prostatitis by massage at the end of treatment of an acute infection in men.

There is always the possibility that there is some form of obstructive lesion in the urinary channels in any case of acute infection. The presence of such a lesion cannot be determined cystoscopically with safety in these cases, since cystoscopy often causes severe damage when done in the course of an acute condition. It is safest in pregnancy and exacerbations of chronic conditions. The history will usually give sufficient indication of a chronic condition, and intravenous pyelography will usually detect an acute obstruction, such as a stone, since sufficient function usually remains in the kidneys, in spite of the pyelonephritis, to secrete the dye.

SUBACUTE AND CHRONIC INFECTIONS OF THE URINARY TRACT

Subacute and chronic infections offer a wider choice of antiseptic drugs than the acute infections do. They also allow time for adequate diagnosis of the condition of the patient, the presence or absence of gross pathologic conditions, and the estimation of the function of the kidneys, both together and as individual organs. It is in this group of infected cases that renal deficiencies are common and gross pathologic conditions, which are often the result of the infections, are encountered. Total renal function is often low, and uremia may be present.

There is a place for mild antiseptic medicines in subacute cases. I make use of hexamethylenamine, without reduction in intake of fluids, for immediate postoperative treatment of residual infection. Doses of $7\frac{1}{2}$ gr. four times daily will prove adequate for clearing many of these infections. It can be safely administered to ambulatory patients. The drug should be confined almost entirely to the treatment of the common infections due to the gram-negative bacilli and acts best at pH 5.3 or below. Increased irritability of the bladder and blood in the urine are the only contraindications to its continued use. These signs and symptoms usually quickly disappear on withdrawal of the medication.

Mandelic acid is also applicable for the treatment of ambulatory patients who have chronic infections. And it is useful for treating some patients who do not tolerate sulfanilamide, although I consider the drug on the whole less effective as an antiseptic, both because of its limited range

in the bacterial field and because it requires a strong acidifier.

Routine administration of a fixed amount of acidifier with mandelic acid is undesirable. Some patients do not need any acidifier at all; some may need it at the beginning of the treatment and then either part or all of it may be withdrawn. Routine use of the acidifier, when the urine is already strongly acid, only hastens signs of renal irritation in some cases, and forces discontinuance of the treatment, which might have been carried to completion under less acidification. Attention to the acidifier by daily pH determinations is the most satisfactory method of administering the drug. Some urines cannot be acidified, because of the urea-splitting bacteria that they contain, no matter how much acidifier is administered. It must be remembered that only the urine is alkaline, and that serious degrees of acidosis may result if the acidifier is pushed in cases that continue to exhibit alkaline urine. When dangerous degrees of acidosis are so produced, the intravenous administration of a 2 per cent solution of sodium bicarbonate is indicated. About forty-eight hours after beginning mandelic acid therapy a fairly stable, low pH is established and remains almost constant, without the usual alkaline flood at mealtime or the other fluctuations noticeable in a normal person.

The sulfanilamide drugs are my choice of treatment for most of the long-standing infections. This is particularly true when the patients can be hospitalized. They are very effectively used during the latter portion of a patient's convalescence in the hospital, when chronic infections are treated after removal of stone or after correction of renal lesions. The amount of drug required is similar to the dosage for acute infections. The staphylococci yield to sulfathiazole more readily than to other drugs of this group, although as yet experience with it has not been so extensive as with sulfanilamide.

UNJUSTIFIABLE USES OF SPECIFIC URINARY-TRACT ANTISEPTICS

Sufficient experience with specific urinary-tract antiseptics has been accumulated to make possible the enumeration of a considerable group of conditions in which their use can be expected to fail to produce a cure. It is proper to call attention to these cases because it is apparent that extensive courses of treatment are often given, with loss of time, considerable expense and no benefit. Table 1 lists 50 consecutive cases in which much unprofitable treatment was given. These cases all exhibited urinary-tract infection. The primary conditions that underlay the infection are

given. These cases emphasize what appears to be a fact; namely, it is seldom wise to continue to treat chronic infections without sufficiently complete diagnosis to indicate the presence or absence of gross disease, and something of the function of the kidneys. It is to be noted that 21 cases were presumably cured after diagnosis and remedial measures had been employed. Five, however, recurred after apparent cure had taken place.

One can state with some confidence that antiseptics can be expected to fail when stasis of

urine exists anywhere in the urinary tract. It is recognized that small degrees of stasis in the ureters, pelves or bladder are not of sufficient importance to negate treatment. For the bladder, a residual urine of 3 ounces probably represents the upper limit. Much smaller amounts of stagnant urine are effective in interfering with treatment when they occur in the pelves and ureters.

Cases on constant drainage offer little chance for sterilizing the urine so long as the drain is kept in place. This is particularly applicable to prostatic hypertrophy and its surgical treatment. The presence of the drainage does not prevent the tissue effect of sulfanilamide from taking place, as evidenced by subsidence of temperature, but does prevent the production of sterile urine.

Stones, large tumors of the bladder and extrinsic conditions that either involve the urinary organs or by encroachment produce abnormal physiologic behavior of the urinary channels are almost certain to interfere with the cure of urinary-tract infections.

Antiseptics cannot be expected to reach closed pus or partially obstructed pus-containing organs in sufficient concentration to clear infection. This group should include abscesses, pyonephrosis, infections of Skene's or Bartholin's gland, prostatitis and perinephritis. Since urinary-tract infections are common in prostatitis and accessory lymph-node infections, recurrence of the urinary-tract infection is, in a large measure, dependent on the cure of the lymph-node infection.

Total renal deficiency, as differentiated from unilateral renal deficiency, offers explanation of the failure to obtain satisfactory results from antiseptics in some cases through inability to produce a therapeutic concentration of the drug in the efferent channels. This group should include some hypertensive and nephritic cases in which there is fixation of specific gravity of the urine. There is also the danger of storage of these potentially harmful drugs. It is almost unbelievable that in most publications on the use of the mandelic acid and sulfanilamide groups of drugs, there is so free an assumption of the normalness of the kidney function when it is so well recognized that infection in chronic form is one of the commonest causes of renal deficiency.

Renal counterbalance will account for a certain proportion of failures in the treatment of infections. In severe degrees of either acute or chronic infections of one kidney, there is a tendency for the drug to escape so completely through the uninfected functioning kidney that an effective concentration of the drug in the affected kidney is not obtained. Such conditions, if chronic, usually call for surgery.

Special types of bacteria are responsible for the failure of cure in some cases. So wide a variation of results is obtained, and they are so unpredictable, that I am inclined to attempt to clear the infection by use of the sulfanilamide group of drugs. I am willing to accept failure and to try other antiseptics.

There are beginning to appear a few cases of rapid rise in nonprotein nitrogen from the normal reading, which preceded administration of the sulfanilamide group of drugs, to dangerous levels. This rise seems to subside promptly on discontinuance of medication. I have personally noted that in three of four cases of pregnancy injury from combined pre-eclampsia and pyelonephritis, when treated for infection some years after delivery, showed nonprotein nitrogen readings as high as 58 mg. per 100 cc. within three or four days after institution of therapy in doses of 40 to 60 gr. daily.

RECURRENCES

In a small group of cases, after cure of infection has been produced and confirmed, there is remote recurrence of infection at periods as long as several months or even years. In 19 of 22 such cases, the bacteria were approximately the same as those in the preceding infections. In one case, there was tonsillitis, for which the surgeon justly did not wish to remove the tonsils. In another, there were unrest and chronic exhaustion. One infection was apt to recur at the time of catamenia, and did so on several occasions many months apart. In two cases, there was diverticulosis of the sigmoid. It seems fair to assume that these cases of frequent remote reinfection are the result of failure to discover and to remedy the causal factors of the original infection. The frequency of occurrence of remote infections in the same cases is too great to justify the assumption that they are accidental occurrences.

SPECIAL GROUPS OF INFECTION

There is sufficient evidence of variation from the average in the clinical findings in some cases to warrant giving them special consideration in treatment by urinary antiseptics.

Cases of prostatic obstruction are so frequently deficient in renal function, and retention of nitrogen is so common, that it is not advisable to treat recent postoperative patients for urinary infection without determination of their renal status. It is in this group of patients that I have seen the most serious results from storage of drugs when an attempt has been made to clear their infections before time had been allowed for improvement of renal function after relief of obstruction.

Prostatitis represents a semiclosed infection. It is often associated with urinary-tract infection. Under treatment by antiseptics the urine is more readily cleared of infection than is the prostate. It is recognized that urinary antiseptics may appear in the prostatic secretions, and therefore that the cure of the prostatitis is theoretically possible. Practically, the results of treatment are not good. The possibility of cure in these patients is improved if they are given a period of massage previous to therapy. Since sulfathiazole is quite effective in staphylococcal infections and since many chronic prostatic infections are of that nature, it is to be hoped that this drug will improve results. Marked improvement has been demonstrated in a limited group of cases.

The ureteral and pelvic dilatations of pregnancy create special conditions for harboring urinary-

tract infections. These infections have long baffled therapeutic measures and antiseptics. The use of cystoscopic therapy has had its chief favorable results here and has had wide application. Mandelic acid therapy is not satisfactory in these cases, because acidosis is already marked in the acute stage of the pyelonephritis of pregnancy. Sulfanilamide has proved of particular effectiveness in these cases, to the extent that cystoscopic therapy has seldom been used at the Boston Lying-in Hospital during the last two years. Diagnostic measures, both by intravenous methods and by cystoscopy, have increased. In the majority of these cases, the renal cortex has sufficient function for producing therapeutic concentrations of the drug for antiseptics, in spite of pyelonephritis and large atonic dilatations of the pelvis and ureter. The function is lowest in severe degrees of pyelonephritis. Storage of the drug may be very rapid and of serious consequence if such a condition is bilateral and the patient shows nitrogen retention. One now obtains cure of the infection in approximately 40 per cent of the cases. Traut, Bayer and McLane* claim cures in 55 per cent of their cases.

The routine treatment is to alkalinize the patients and to raise their fluid intake to 3500 or 4500 cc. daily. Sulfanilamide is administered in doses of 40 to 60 gr. daily, without attempting to concentrate the urine, and being careful to maintain alkalinization. The treatment is for a period of seven days. Three types of results are produced. In 40 per cent, there is cure of the infection. However, since stasis is the important etiologic factor in the infections of pregnancy, there are a number of cases in which reinfection occurs one or more times during the remainder of the pregnancy. A second group of cases shows diminution and usually cessation of symptoms, but the urine remains cloudy. Another group shows loss of pus, but the infection remains as a bacilluria. It is important to recognize the futility of treating gross pathologic conditions in these cases, except for symptomatic relief. Doses of 60 gr. of sulfanilamide a day are usually preferable to smaller ones. Few cases show improvement if the administration of sulfanilamide is continued beyond a week.

Recent surveys of cases of pyelonephritis of pregnancy indicate that there is almost as much likelihood that mild infections in pregnancy will evidence as much renal damage some years after the injury as severe cases. It is incumbent on those in charge of such patients to treat the women

who have bacilluria and mild infections but who may have no symptoms as actively as they do the febrile cases. Sufficient observation should be given to all post-partum cases for three to four months following delivery to determine whether the infection has cleared. In those cases in which there is delayed retrogression of the dilatations of the pelvis and ureters, reinfection may occur at any time. If it takes place after demonstration of absence of infection, one may rest in a sense of false security. In some of these apparently cured patients, review of the cases after several years may demonstrate extensive damage to the pelvis and ureters, and persistence of the infection.

SUMMARY

Clinical experience with the more recent additions to the list of urinary antiseptics indicates their increased potency, both for good and harm, over older antiseptics. There is some specificity worthy of the name in these drugs, but it is only relative. There are conditions of renal disease and disordered function in the urinary tract in which cure often cannot be produced by any of the antiseptics. Cure can be accomplished in a considerable number of such cases when, after adequate diagnosis of pathologic and physiologic conditions of the urinary tract, proper remedial measures have been applied or advantage of this information has been taken for better administration of the antiseptic.

99 Commonwealth Avenue

DISCUSSION

DR. GEORGE GILBERT SMITH, BOSTON: With the views expressed by Dr. Crabtree I am in almost complete agreement. He has done well to emphasize two points: the necessity for thorough study of the patient before subjecting him to treatment, and the danger that attends the unwise use of these newer urinary antiseptics. In the early days of sulfanilamide therapy it was reported to be the custom in a hospital remote from here to treat all admissions with sulfanilamide. If they showed no improvement after a few days, a history was taken and a physical examination was made. This may have been a slight exaggeration, but was probably not far from the truth in a good many cases.

The calamities resulting from the unguarded use of sulfanilamide have probably been more numerous than we shall ever know. The chief danger is that of causing agranulocytosis; this may be guarded against by doing a white-cell count at least twice a week. Sudden, fulminating destruction of red blood cells has been reported, but is probably much less frequent than agranulocytosis. The appearance of the patient and determining of the hemoglobin percentage will warn the physician of the development of anemia.

A peculiarity of sulfanilamide that has made its use in a sense disappointing is the temporary nature of the improvement brought about by its administration. This condition exists in gonococcal infections as well as in those of

*Traut, H. F., Bayer, D. S. and McLane, G. M. The prophylaxis of pyelo-urethritis gravidarum. *I. A. M. A.* 115:94-97, 1940.

the upper urinary tract. The sudden clearing of the urine or the disappearance of urethral discharge raises false hopes in the minds of both physician and patient. Experience has taught us to discount this apparent improvement; the drug must be continued for several weeks at least, although the dosage may be decreased to 15 or 20 gr. a day. I have a patient who a year ago was almost incapacitated by recurring attacks of pyelonephritis. He has been taking this amount of sulfanilamide for over a year. To all appearances he is well, but his urine still shows a positive culture for colon bacilli.

It has seemed to me that mandelic acid, if it can be tolerated by the patient, gives more permanent results in removing colon bacilli from the urinary tract than does sulfanilamide. The necessity for concentrating the urine

and for keeping it at a pH of 5.3, as Dr. Crabtree has pointed out, makes the administration of mandelic acid somewhat more arduous.

In our enthusiasm for these potent urinary antiseptics we are likely to forget some of the less spectacular but nevertheless useful chemicals. Methenamine, as Dr. Crabtree has said, has cleared up many colon bacillus infections in the past. Serenium has proved very satisfactory in a number of patients, and can be given without fear of complications. With the rapid development of new derivatives of sulfanilamide, we find ourselves somewhat bewildered by the claims of their originators. The wisest course is to stick to the preparation that we have learned to use until others have been definitely proved to be better.

TREATMENT OF MENINGOCOCCAL MENINGITIS*

EDWIN H. PLACE, M.D.†

BOSTON

SINCE Flexner¹ in 1908 first reported his series of cases of meningococcal meningitis treated with antimeningococcus serum, there has been a general acceptance of the influence of serum treatment in this disease. Table 1 gives the comparative results in the earlier years, with a reduction in mortality of nearly 40 per cent in the serum-treated cases.

In the Boston epidemic of 1904-1907 the mortality in 181 cases treated at the Boston City Hospital was 67.3 per cent. In the succeeding eight years the mortality in 50 endemic cases was 58 per cent. The

treated cases was 54 per cent, and in 102 untreated it was 82 per cent.

The reduction in mortality, however, since the introduction of antiserum treatment has been far from satisfactory. In Massachusetts, from 1926 to 1938, in 1474 cases the mortality was 42 per cent, varying in yearly levels from 30 to 66 per cent.⁵ In Chicago, from 1916 to 1935, the mortality was 47.7 per cent in 4028 cases (Hoyne⁶); in Detroit, from 1928 to 1931, it was 50.5 per cent in 1686 cases⁶; and in New Orleans, from 1925 to 1934, it was 65 per cent in 221 cases (Tripoli⁷).

The relatively unsatisfactory effects of serum treatment may be due to several causes. In the first place, the serum may not contain an effective level of antibodies for the type of meningococcus causing the infection. The polyvalent serums usually used in this country are produced by the injection into horses of a number of strains, often twelve or more, but the antibody response to each strain may be strikingly different. Furthermore, there is no satisfactory measure of the therapeutic value of antimeningococcus serum except the clinical effect. Wright et al.⁸ failed to find that determination of the level of agglutinins was of value in measuring the clinical effectiveness of antiserum. Miller's⁹ method of raising the virulence of meningococci with mucin so that they are pathogenic for mice has introduced the possibility of using mouse-protection tests as a measure of potency, but the clinical value of this technic has not been determined. Secondly, the serum may not reach the organisms throughout the subarachnoid space. Meningococci may be walled off in islands of fibrin, and recurrences and relapses occur in about 5 per cent of the cases after apparent clear-

natural course of this form of meningeal infection is much better than that due to infections with other bacteria but has shown great variation, with mortalities ranging from 40 to 90 per cent. In an epidemic in South China Olitsky³ reported a mortality of 84.6 per cent in 104 cases without treatment and of 54.1 per cent in 346 cases with lumbar puncture only. Cormack⁴ recently reported an epidemic in Africa in which, due to lack of serum, only a part of the cases were treated; the mortality in 139

ing. The intravenous route has generally been considered unsuited for an antiserum because of the supposed blood-brain barrier (Stern et al.,¹⁰ Mutermilch and Salamon,¹¹ and Freund¹²). Friedemann et al.¹³ have recently shown, however, by ingenious experiments that the blood-brain barrier does not exist for antitoxins, and Hoyne⁶ has secured very low mortality rates by intravenous administration alone. Table 2 shows the comparative

results of serum treatment by different routes Hoyne, in 43 cases under twenty years of age treated intravenously, reported a record mortality of 23 per cent.

There is great difficulty in evaluating results because of variation in virulence and type of the organisms, the use of different amounts of serum of varying antibody titers and the difference in the patients' ages and in the time of treatment. The

TABLE 3 *Effect of Time of Treatment, According to Age.*

mortality below one year of age and above forty years is very high, and that above fifty years approximates 100 per cent. Flexner¹ showed the importance of early treatment, which was especially marked during infancy (Table 3).

The value of Ferry's¹⁹ antitoxin as compared to an antiserum still remains uncertain. In 1936 Hoyne⁶ reported 201 antitoxin-treated cases, with a mortality of 27 per cent. He gives large doses intravenously—50,000 to 100,000 units (150 to 300 cc). Banks²⁰ had a mortality of 28 per cent in 25 cases treated with antitoxin. A number of reports of antitoxin

treatment of meningitis, usually of small numbers of patients, have shown good results, but due either to lack of controls or to obvious differences in age or time of treatment in the groups the figures are not dependable. Ferry's antitoxin contains antibacterial antibodies, and Zinsser²¹ believed that "the therapeutic activity of so-called meningococcus antitoxin is due to the presence of antibacterial and antienterotoxin antibodies."

For intraspinal use, the dose naturally is limited, and variation of dosage must be secured by injection at different intervals. Bolduan¹⁴ at Bellevue Hospital showed much better results with twelve-hour (7 per cent mortality) than with twenty-four-hour (23 per cent mortality) intervals.

In the recent Boston epidemic the mortality was 48 per cent, with eight-hour to twelve-hour intervals.

Some workers believe that overtreatment may do harm. In judging the discontinuance of serum therapy, a drop in the number of cells and in the amount of cerebrospinal fluid, disappearance of the organism in culture and clinical improvement must all be considered. Since serum reactions may keep up the pleocytosis and an increase in the amount of cerebrospinal fluid, the chief dependence must be on smears and cultures.

During the last three years, sulfanilamide has been used with a generally lower mortality than that secured with serum (Table 4).

Branham and Rosenthal²⁵ have shown experi-

TABLE 5 *Effect of Combined Serum and Sulfanilamide Therapy.*

AUTHORITY	No OF CASES	MORTALITY

mentally in mice that serum and sulfanilamide together were more effective than sulfanilamide alone in four of ten strains. Similar results were obtained by Brown.²⁶ Clinically no clear evidence has been secured that serum is usually necessary

when sulfanilamide is used. But since occasional cases may not respond to the drug treatment, it may be desirable to use serum, although probably only small amounts will be needed. Table 5 shows the results of combined serum and sulfanilamide therapy; the average mortality rate is the same as that for sulfanilamide alone.

One of the most striking effects of sulfanilamide treatment is the rapid subsidence of symptoms and the spinal-fluid pleocytosis, and the rapid disappearance of the organisms from the blood and spinal fluid, usually in twenty-four hours. Blackfan² found in 33 cases treated with anti-meningococcus serum that organisms could be recovered after the third day in 51 per cent, and Levy³¹ in 144 cases recovered meningococci after the third day in 24 per cent. In the 25 cases treated by us with sulfanilamide no organisms could be recovered after the third day, except in one case.

Relapses after serum treatment were reported by Flexner¹ in 4.5 per cent of 427 cases, and Worster-Drought and Kennedy³² reported relapses in 5 per cent. Tillett and Brown¹⁸ in the Baltimore epidemic, in which they used a very effective serum, still had recrudescences or relapses in 11.5 per cent. Relapses and recurrences after sulfanilamide have been reported in only 0.5 per cent,^{20, 22-28} and these have occurred without exception with inadequate treatment. The drug should promptly reach a level in the spinal fluid of 5 to 10 mg. per 100 cc., although lower concentrations are often effective.

Oral administration is entirely satisfactory; if vomiting is present, the drug may be given subcutaneously in 0.8 per cent solution or intrathecally.

Untoward effects of the drug must be continually watched for. These are too well known to require review. In our series they were rarely significant. The use of sulfanilamide alone has given an opportunity to judge the harmful effects of intrathecal serum, as distinguished from local effects of the disease itself. Although our experience has been too small for satisfactory analysis, we were struck by the decrease in spinal-fluid block and in myelitic and cerebral damage and by the absence of pressure abnormalities in the sulfanilamide-treated cases. The same effect has been noted by Hoyne⁶ following intravenous serum therapy as contrasted with intrathecal treatment.

Meningococcemia has disappeared promptly following sulfanilamide treatment, even in cases found resistant to serum therapy.

Meningococcal arthritis usually tends to subside, even without efficient therapy. Tillett and Brown¹⁸ found arthritis in 43 per cent of their cases. All cleared, though some slowly, with intravenous and intrathecal therapy. Sufficient evidence of

control of arthritis by chemotherapy is still lacking, but our cases have shown rapid subsidence. Schein²³ in a recent report of 23 cases of meningococcal arthritis discredits somewhat the optimistic prognostic view so generally held. Several of his cases had persistent trouble and in 3, or 13 per cent, there was permanent joint damage, with destruction and ankylosis. In 2 cases of severe purulent meningococcal arthritis we have followed the technic, so successfully used in streptococcal arthritis, of mechanically washing out the joint, with prompt and complete recovery.

The dosage of sulfanilamide recommended by Long and Bliss³⁴ seems adequate:

WEIGHT OF PATIENT	INITIAL DOSE	SUBSEQUENT 4-Hr. DOSE
<i>lb.</i>	<i>gr.</i>	<i>gr.</i>
100 or more	50-80	15
50-90	30-50	10-15
25-50	20-30	5-10

The advantages of sulfanilamide are that administration is simple; it is independent (largely) of type of organism; the dosage can be reasonably accurate, and the concentration is measurable; inadequacy of original titer or loss from keeping, as in serum, is excluded; the drug is much cheaper; the mortality is lower; there is apparently less neurologic damage.

SKIN MANIFESTATIONS DUE TO SULFANILAMIDE AND ITS DERIVATIVES*

ARTHUR M. GREENWOOD, MD †

BOSTON

IT is possible roughly to classify the effects on the skin of the therapeutic use of sulfanilamide and its derivatives under the three categories suggested by Loewy¹ in a discussion of the effects of prolonged administration of drugs. These are the direct toxic effects due to overdose and cumulation, the purely allergic effects, producing manifestations identical with those seen in consequence of antigen antibody reactions in protein anaphylaxis, and the allergototoxic effects. In the first category an overdose can usually be excluded and a peculiar sensitivity due to gradual sensitization is evident. The manifestations are different from the purely allergic, anaphylactic reactions, and are fairly characteristic for the cumulative drug, which probably acts indirectly on the protein metabolism. Such an allergotoxic effect is responsible for most drug idiosyncrasies.

The accuracy of such a classification is debatable, and in the use of sulfanilamide particularly, the accompanying rashes are so multiform that hard and fast categories cannot be adhered to, so far as objective appearance of the eruption is concerned. There is no single rash characteristic of sulfanilamide and its derivatives.

Without seeming to be too definite, one may say that in many cases the first manifestations of the toxic type of eruption are shown by a faint, finely papular rash on the arms—perhaps accompanied by mild itching and fever. If the drug is continued, the rash spreads and becomes maculopapular, scarlatiniform or morbilliform. It may involve the whole body or may be limited to various parts. There is no lymphadenitis accompanying it. On cessation of the drug, the fever goes

and with it the rash, occasionally leaving the involved surfaces desquamating—at other times leaving no trace. In certain cases the rash disappears even though the drug is continued. In others, after cessation of sulfanilamide and the disappearance of the rash, the drug may be resumed in moderate dosage without untoward symptoms. Such cases may be considered to be due to direct toxicity of the drug, either from primary overdose for the patient or from accumulation. There is no allergy and no gradually built-up sensitization.

Cases illustrative of the second type, the purely allergic effect, show early in the course of administration of sulfanilamide intense itching, sneezing, lachrymation and dyspnea, with edema of the lips, eyelids and face. The eruption may be urticarial, hemorrhagic or bullous. Patch and scratch tests may be positive for the drug.

Cases showing the allergotoxic effect, that of gradual sensitization, ordinarily appear later in the course of therapy—from the seventh to the fourteenth day of average dosage of sulfanilamide. The eruption is generally maculopapular and accompanied with pruritus and urticarial lesions, with fever and, in some cases, leukocytosis. Resumption of sulfanilamide, after cessation and the disappearance of the rash, is quite certain to bring on a recurrence of the reaction.

All reports and observation show the multiform character of sulfanilamide rashes. They may be erythematous, papular, morbilliform, scarlatiniform, urticarial, petechial or bullous; the mucous membranes may be affected; the rash may be limited or general, accompanied or unaccompanied by fever and itching. Exfoliative dermatitis has been a sequel in some cases. One case has been

*Presented at the annual meeting of the Massachusetts Medical Society Boston May 22 1940

†Dermatologist New England Deaconess Hospital

reported in which a fixed eruption was produced by sulfanilamide and sulfapyridine.² Most cases, however, are maculopapular, not generalized, and are accompanied by fever and pruritus. Although there is no specific characteristic for the rash, numerous reports and my own observations stress its peculiar, almost maroon color in many cases, and this very intensity of the superficial vascular reaction in a fully developed case constitutes an identifying factor.

In spite of this lack of specificity of the lesions, it is not difficult to make the correct diagnosis of the eruption appearing in the course of treatment, and the only difficulty is to distinguish the morbilliform type from measles and the scarlatiniform type from scarlet fever. It has been noted that the average interval between beginning administration of the drug and the appearance of the rash falls within the period of incubation of the common infectious fevers.³ With a morbilliform sulfanilamide rash, however, Koplik's spots, catarrhal symptoms and lymphadenitis are not present, and in a scarlatiniform rash the characteristic tongue and throat of scarlet fever are absent.

There is some evidence to show that persons sensitive to local anesthetics and those who have had other drug rashes are likelier to be sensitive to sulfanilamide.

The eruption is likely to occur in from 2 to 6 per cent of cases treated with average dosage, with a higher incidence, 30 per cent, in cases intensively treated.⁴ It has been shown that sulfanilamide in certain concentration and in certain persons is a photosensitizing agent and that in such patients the rash is confined to exposed surfaces, or is more intense over such areas.^{5, 6} Although not all cases of sulfanilamide eruption can be considered to be dependent on exposure to sunlight, it is definitely advisable that all patients under sulfanilamide therapy be protected from direct sunlight or ultraviolet radiation.

It has been found that in certain cases of sulfanilamide dermatitis there is an increase in urinary porphyrins.^{7, 8} Such increases, however, may occur in association with various disorders accompanied by severe derangement of the general metabolism, and increased values are not found in all cases of sulfanilamide dermatitis. Long and Bliss⁹ state that in their opinion the role played by the production of porphyrins in sulfanilamide dermatitis has not been investigated sufficiently to warrant a final word on the subject. Brunsting⁸ says that whereas light sensitization and porphyria may appear at the same time there is no evidence to show that one condition is dependent on the other.

In the use of sulfathiazole apparently a some-

what higher incidence of skin reactions is to be expected. Haviland and Long¹⁰ report 12.8 per cent of eruption and state that the rashes fall in three groups—maculopapular, urticarial and those like erythema nodosum. This last group has not been reported in connection with sulfanilamide or sulfapyridine medication. They also report a new type of reaction with this drug—a conjunctival and scleral injection restricted mainly to the exposed portion of the bulbar conjunctiva and sclera, and in some cases apparently dependent on exposure to light. I have seen one such case, in which there was pronounced congestion and edema of the ocular and palpebral parts of the conjunctiva occurring on the ninth day of sulfathiazole medication, in a patient confined to the ward and in whom a very slight rash appeared. Of 13 cases treated at the Massachusetts General Hospital with sulfathiazole in moderate dosage, 6 showed a rash—a much higher incidence than has previously been reported.

SUMMARY

It can be said that the rashes occurring in the course of therapy with sulfanilamide or its derivatives are multiform in character and are not specific, with the possible exception of those following the use of sulfathiazole; that they may be manifestations of toxemia, sensitization or allergy; that they may occur at any time in the course of treatment, but generally from the fourth to the fourteenth day, and in from 2 to 30 per cent of the cases, depending on the intensity of treatment. They are likelier to appear in areas exposed to sunlight and may be accompanied by an increase in the excretion of porphyrins. The occurrence of a rash is a warning of danger, and treatment with sulfanilamide or its derivatives should be stopped and not renewed unless the gravity of the case warrants it; if treatment is to be resumed the patient should be tested for sensitivity with small (0.3 gr.) doses of the drug.

CRIMINAL ASPECTS OF FAITH HEALING

I. H. RUBENSTEIN*

CHICAGO

THE question that this article seeks to answer is, What are the criminal aspects of faith healing and its practice, particularly when infant children die as a result of lack of medical care that their parents refuse to provide because of their religious convictions as members of a faith-healing cult? To understand the several criminal aspects of this question, it is necessary to know what faith healing means. Faith healing is simply the treatment of human ailments, injuries and diseases by mental and spiritual means, that is, by mental "reasoning," argument and prayer. Because of the strong emotional appeal that faith healing has for the public in general, this age-old doctrine has been exploited by numerous "founders and discoverers" of faith-healing sects, especially in the last hundred years.

The first point to consider in this article, therefore, is how the courts have viewed the subject of faith healing itself. In a Pennsylvania case,¹ the court stated:

Common faith of mankind relies not only upon prayer, but [also medical care]. . . . Our laws recognize disease as a grim reality to be met and grappled with as such. . . . It may be said that the wisdom or folly of depending upon the power of inaudible prayer alone, in the cure of disease, is for the parties who invoke such a remedy. But this is not wholly true. "For none of us liveth to himself, and no man dieth to himself," and the consequence of leaving disease to run unchecked in the community is so serious that sound public policy forbids it. Neither the law, nor reason, has any objection to the offering of prayer for the recovery of the sick. But in many cases both law and common sense require the use of other means [medical care] which have been given to us for the healing of sickness and the cure of disease. There is ample room for the office of prayer, in seeking for the blessing of restored health, even when we have faithfully and conscientiously used all the means known to science and the art of medicine.

As clearly indicated by the reasoning of the court in this case, faith healing constitutes a grave menace and danger to the public health, when used as a substitute for medical care, especially when infectious and contagious diseases are involved. For this reason, as well as others, the courts have viewed with strong disfavor,² and have even condemned,³ any institution that encourages the growth and spread of faith healing. At present,

the law is well established that as a matter of public policy the proper public authorities may restrict and even prohibit the practice of faith healing if it should in any way endanger the public health.⁴

Having given sufficient consideration to the subject of faith healing itself, the next point to consider is whether the practice of faith healing constitutes a violation of the several medical-practice acts. Although practically all the medical-practice acts expressly exempt "those persons who endeavor to heal or cure the sick and suffering by prayer or spiritual means or as an exercise of the tenets of their religion" from their penal provisions, a large number of faith healers of various cults have been convicted in many states on criminal charges for violation of these acts.⁵ In those cases in which the courts have held that faith healers do come within this statutory exemption, the treatment is exclusively spiritual and religious,⁶—that is, confined solely to prayer,⁷—and is not accompanied by the use of any physical means whatever. A faith healer would therefore be subject to the penal provisions of any of the several medical-practice acts if he also made use of any of the following physical agencies or means: giving a diagnosis of the patient's ailment, injury or disease,⁸ giving treatment based on such a diagnosis,⁹ asking pertinent questions of the patient as to his ailment, giving massage,¹⁰ recommending or giving any herbs, liquids,¹¹ chemical preparations,¹² or physical exercises, using any physical instrument, giving directions as to food or diet,¹³ or directly advising the patient to discontinue or abstain from medical or surgical treatment.¹⁴ Faith healers may also be prohibited from giving treatments that might endanger the public health,⁴ especially if they are violative of statutory quarantine and sanitary regulations. Even in those cases in which the faith healer confines his treatments exclusively to spiritual means, he may be subject as an offender of the medical-practice act when it is shown that he is exploiting faith healing for commercial profit. As was well stated by a Colorado court¹⁴:

One is not authorized . . . under the cover of religion or a religious exercise . . . to go into healing commercially for hire, using prayer as the curative agency or treatment. Religion cannot be used as a

*Member of the Chicago Bar.

shield to cover a business undertaking.* . . . The practice of medicine, defined by our statute, means the practice of the healing art commercially, regardless of the curative agency employed.† The commercial practice of healing by prayer, followed as a money-making venture or occupation, is the practice of medicine within the plain meaning of the statute.¹⁵

This ruling is particularly applicable when the faith healer gives treatments to his patients in an office building, apart from his own home or the home of the patient, or in the church edifice, and there charges compensation for his treatments.¹⁶

When a faith healer is prosecuted for a criminal violation of the medical-practice act, the issue of constitutional religious freedom is always raised. On this point, however, the law is well settled: although the government may not interfere with mere religious belief and opinions, it can prohibit and punish religious practices that are criminal offenses.‡ Since the violation of a state medical-practice act is a criminal offense, it can readily be seen that a faith healer whose practices make him guilty of such an offense⁵ may not claim the defense of constitutional religious freedom.¹⁹

The next and most important point for consideration is the criminal responsibility of parents who allow their infant children to die as a result of their refusal to provide them with the necessary medical care, because of a conscientious belief in faith healing. Under the law, medicines and medical attention furnished an infant, when his health or physical condition requires them, are necessities because they answer the bodily needs of the infant.²⁰§ By the law of Nature, as well as the common law, and independently of statute,

*A school for training faith healers was held irreligious because founded solely for the pecuniary benefit of its founders and officers.³

†The giving of treatment by a faith healer for a fee constitutes the practice of medicine and makes the faith healer subject to criminal prosecution.¹⁵

‡The First Amendment to the Constitution of the United States declares that "Congress shall make no law respecting an establishment of religion or prohibiting the free exercise thereof." This amendment, which guarantees religious liberty and which exists in similar paraphrased form in all the state constitutions, has been interpreted to mean "to allow everyone under the jurisdiction of the United States to entertain such notions respecting his relations to his Maker and the duties they impose as may be approved by his judgment and conscience, and to exhibit his sentiments in such form of worship as he may think proper, not injurious to the equal rights of others, and to prohibit legislation for the support of any religious tenets, or the modes of worship of any sect . . . It was never intended or supposed that the Amendment could be invoked as a protection against legislation for the punishment of acts inimical to the peace, good order and morals of society . . . However free the exercise of religion may be, it must be subordinate to the criminal laws of the country, passed with reference to actions regarded by general consent as properly the subjects of punitive legislation . . . Should a sect [with tenets encouraging crime] ever find its way into this country, swift punishment would follow the carrying into effect of its doctrines, and no heed would be given to the pretence that, as religious belief, their supporters could be protected in the exercise by the Constitution of the United States."¹⁷ "To permit a man to excuse his criminal practices because of his religious belief . . . would be to make the professed doctrines of religious belief superior to the law of land, and in effect permit every citizen to become a law unto himself. Government could exist only in name under such circumstances."¹⁸ Therefore no plea of religion can shield a person who commits a criminal offense, because the public would be at the mercy of superstition, if criminal offenses could be "committed with impunity, because sanctioned by some religious delusion."¹⁹

§"It is undisputed that medicine is a science, is now and has been for a long period of time, generally recognized by the law, and the efficacy of medical treatment by a skilled and competent physician is universally conceded."²¹

it may be generally stated that parents are under an obligation to care for their young in sickness and in health, and to do whatever may be required for their care and maintenance, including medical attendance if necessary. The failure to provide such medical care is a public wrong, and if the infant child is injured, the parent can be convicted of the criminal neglect of his child¶; should the child die as a result of such neglect, the parent would be guilty of manslaughter.²³ The law is the same in such cases, even though the neglect of the parents was due entirely to their superstitious or conscientious opinions that it is wrong and irreligious to provide medical aid for their children or themselves.²⁴ In other words, the law may be stated to be that a parent, guardian, relative or any other person, who has the custody of a person "who is unable, by reason of . . . age . . . to withdraw himself from such charge, [is under a duty] to supply that person with the necessities of life, medical attention . . . included, and that where one by reason of his religious belief fails to provide medical treatment for a child, he may in case of the death of the child, be convicted of manslaughter."²⁵¶¶

In the leading English case,²⁶ the defendant was the father of an eight-month-old infant. The child died of diarrhea and pneumonia. The prisoner had not supplied his child with any medical care, because he was a member of a sect, called the "Peculiar People," which believed in faith healing and disbelieved in the necessity of physicians and medicines. The medical testimony was that medical assistance would certainly have prolonged and in all probability would have saved the child's life. The prisoner was indicted under a Prevention of Cruelty to Children Act, which read: "If any person . . . who has the custody, charge or care of any child . . . wilfully . . . neglects . . . such child . . . in a manner likely to cause such child . . . injury to health, that person shall be guilty of a misdemeanor." The prisoner was convicted of manslaughter. In affirming the manslaughter conviction, the eminent Chief Justice Lord Russell declared:

The [meaning of the] words in the statute, "wilfully neglects" . . . is very clear. "Wilfully" means that the act is done deliberately and intentionally, not by accident or inadvertence, but so that the mind of the person who does the act goes with it. "Neglect" is the want of reasonable care, that is, the omission of such steps as a reasonable parent would take, such as are

¶A father, who refused to allow his infant child to be operated on for adenoids, which were impairing the child's health, was held to be liable for criminally neglecting to provide his child with medical care.²³

¶¶To sustain a manslaughter conviction in these cases, it is necessary for the medical testimony to show that the neglect to obtain medical care hastened or caused the death of the child, and not merely that the medical care would have prolonged the life of the child.

usually taken in the ordinary experience of mankind, that is, in such a case as the present. At the present day, when medical aid is within the reach of the humblest and poorest members of the community, it cannot reasonably be suggested that the omission to provide medical aid for a dying child does not amount to neglect. Mr. Sutton [counsel for the prisoner] contended that because the prisoner was proved to be an affectionate parent, and was willing to do all things for the benefit of his child except the one thing which was necessary in the present case, he ought not to be found guilty of the offense of manslaughter, on the ground that he abstained from providing medical aid for his child in consequence of his peculiar views in the matter, but we cannot shut our eyes to the danger which might arise if we were to accede to that argument, for where is the line to be drawn? In the present case, the prisoner is shown to have had an objection to the use of medicine, but other crises might arise, such, for instance, as the case of a child with a broken thigh, where a surgical operation was necessary, which had to be performed with the aid of an anesthetic. Could the father refuse to allow the anesthetic to be administered? Or take the case of a child that was in danger of suffocation, so that the operation of tracheotomy was necessary in order to save its life, and an anesthetic was required to be administered. I am of the opinion the conviction ought to be affirmed.

Likewise in accord with the preceding authoritative English case is the leading Canadian case.²⁷ Here, the defendant was a Christian Scientist. He was the father of a six year-old boy. The child was ill with diphtheria and subsequently died of the disease. During the time that the boy was ill, he was given Christian Science treatments by a Christian Science "demonstrator." The prisoner, a man of financial means, admitted that if he had not been a Christian Scientist, he would have called in a physician. He was indicted under the criminal code for failing to supply necessities for his child, that is, to provide medical care, and he was convicted of manslaughter. In affirming the conviction, the Ontario Court of Appeals declared

No matter how earnestly a parent might believe in the efficacy of Christian Science treatment, as developed in Mrs. Eddy's handbook of the doctrines of the sect, yet if they came to the conclusion that medical aid and treatment was necessary, they ought also to find that it would not be furnished by means of mental treatment by a Christian Science demonstrator. Persons sui juris may by mutual consent, and within certain limits, practice upon each other what experiments of this kind they please. But it would be shocking if in the case of infants or others incapable of protecting themselves, they and the community in which they live were to be exposed to the danger from contagious or infectious diseases which the instructed common sense of mankind in general does not as yet find or admit to be curable by means only of subjective or mental treatment.

Also in accord with the reasoning of the English and Canadian authorities are the American

courts. In the leading American case,²⁸ the defendant had a sixteen month old daughter, who contracted whooping cough, which afflicted her for thirty days, when catarrhal pneumonia developed and caused her death three days later. The defendant testified that forty eight hours before the child died, he observed that her symptoms were of a dangerous character, but that he did not send for or call a physician to treat her, although he was financially able to do so. His reasons for not doing so were that he was a member of a faith healing sect, known as the Christian Catholic Church, the teachings of which denied the need of medical aid, and that his religion led him to believe that the child would get well by prayer. The defendant was indicted and convicted of a misdemeanor. In affirming the conviction, the Court of Appeals of New York declared

The peace and safety of the state involves the protection of the lives and health of its children as well as the obedience to its laws. Children when borne into the world are utterly helpless, having neither the power to cure for, protect or maintain themselves. They are exposed to all the ills to which the flesh is heir, and require careful nursing, and at all times, when danger is present, the help of an experienced physician.

A person cannot, under the belief or profession of [religious] belief that he should be relieved from the care of children, be excused from punishment for slaying those who have been borne to him.

Although the father was convicted only of a misdemeanor, one commentator²⁹ stated that it does not appear why the father "was not indicted for manslaughter, since his child died as a result of his failure to provide medical aid."

In two Pennsylvania cases,^{30 31} in which the facts were similar to the Pierson case, the conviction of the father on manslaughter charges was affirmed. In its reasoning for its decision, one Pennsylvania court³⁰ declared

If the case of sickness be such that ordinary prudence would suggest the services of a physician and the use of proper medicines, then such services and medicines would be necessities in that case, and failure to employ the one and use the other, if reasonably within reach, would be negligence on the part of the person on whom the duty rested and if by reason of such neglect on the part of the father, the death of a child ensues, he would be guilty of manslaughter.

In the other case,³¹ the court stated that the father cannot relieve himself of his legal duty to provide medical care to his child,

because of some religious or conscientious belief. In no instance is this more true than in the case of a helpless infant unable to take any action for its own assistance or relief and incapable of exercising judgment as to what should be done. If persons were permitted

to plead, as giving them immunity from acting contrary to enactments of law, their religious belief, . . . the whole policy of the state relative to health laws would be defeated.

Because such neglect on the part of a parent to provide the necessary medical care to his infant child is pursuant to a religious belief, and is a religious practice, which nonetheless is a criminal offense,²⁵ the defense of constitutional religious freedom is of no avail in such cases.¹⁷⁻¹⁹ If the infant child dies, the faith healer can be convicted as an accomplice, as an accessory before the fact,³² or even as a principal, on manslaughter charges, if the evidence shows that, in addition to prayer, he made use of any physical means or agency.*

*In two cases,³³ faith healers were acquitted because they confined their treatments exclusively and solely to prayer.

MEDICAL PROGRESS

UNCOMMON INFECTIOUS DISEASES IN NEW ENGLAND*

CHESTER S. KEEFER, M.D.†

BOSTON

SINCE 1921, several infectious diseases have been recognized with increasing frequency in the United States. These include rat-bite fever, rickettsial diseases, Weil's disease, tularemia and brucellosis. Inasmuch as all these infections have been encountered in New England during the past few years, it seems proper and fitting that a few of the more important features and advances that have been recorded recently should be reviewed at this time.

HAVERHILL AND RAT-BITE FEVERS

In 1926, Place, Sutton and Willner¹ described an epidemic of illness in Haverhill, Massachusetts, which was characterized by fever, a skin eruption and arthritis. Parker and Hudson² isolated from the circulating blood and joints of these patients

an organism that was found to be identical with *Streptobacillus moniliformis*, which had been isolated independently from a single case by Levaditi, Nicolau and Poincloux.³ The blood of patients recovering from this disease also contained agglutinins against this particular organism. Previous to these observations Schottmüller,⁴ Blake⁵ and others had described a form of rat-bite fever in man that resembled in many respects the clinical features of the cases reported by Place, Sutton and Willner,^{1, 6} and the organisms isolated from these cases were similar to those obtained from the latter. More recently, organisms identical with those described in so-called "Haverhill fever" have been isolated from infections following rat bites in man^{7, 8}; and they have also been found in the arthritis of spontaneous polyarticular rheumatism in mice.^{9, 10} It seems clear, then, that mice and rats harbor this organism in their mouths, and that they may suffer from a form of arthritis as a re-

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Wade Professor of Medicine, Boston University School of Medicine; director, Evans Memorial, Massachusetts Memorial Hospitals.

sult of the infection. Moreover, following the bite of a rat, a form of rat-bite fever may develop in man that may resemble in all respects Haverhill fever.

One of the curious features about the Haverhill epidemic was the fact that it was thought to be due to the ingestion of infected milk; it is possible that the milk had become contaminated from a milker, since the first person known to have had the disease was found on a farm supplying raw milk to the community that was subsequently involved in the illness. It was also discovered that one cow on his farm had agglutinins in the blood against the organism causing the disease; however, the cow was disposed of before additional examinations could be made. It was suggested, of course, that the milk might have been infected from contact with rats and mice or even a human case. However, another possibility must certainly be considered in the future, namely, the occurrence of this organism or of one closely related to it in cows' milk.

In 1935, Klieneberger¹¹ was able to demonstrate a "pleuropneumonia-like organism" in all cultures of *S. moniliformis*. These organisms were designated as "L forms," and she considered them to be natural symbionts in all infections due to *S. moniliformis*. Other students of this organism have confirmed Klieneberger's valuable observations, but there have been several dissenting views concerning the interpretation of the significance of the L forms. Instead of accepting the interpretation of L forms as being due to distinct organisms, and therefore symbionts, it has been suggested that they are variants of the streptobacillus.^{8, 12} This matter requires further study, but if it can be demonstrated that organisms resembling those causing pleuropneumonia in cattle can be converted into streptobacilli, the possibility of human infection from milk becomes much more significant. Thus it may be seen that pleuropneumonia in cattle or *S. moniliformis* infection in rats or mice may be the sources of infection for a form of rat-bite fever in man or for cases of Haverhill fever. The clinical differences may be due to the portal of entry of the organism. To avoid confusion, it is suggested that these cases be called *S. moniliformis* infections rather than rat-bite fever or Haverhill fever.

It is well in any patient who has fever, skin eruption and arthritis to consider the possibility of *S. moniliformis* infection. If there has been a history of a recent bite by a mouse or a rat, or of the ingestion of raw milk, the diagnosis becomes likely. It can be established with certainty by isolating the organism from the blood or synovial

fluid or by detecting agglutinins in the circulating blood.

RICKETTSIAL DISEASES

Typhus and Rocky Mountain Spotted Fever

One of the major advances in the study of typhus and Rocky Mountain spotted fever during the last year was the announcement by Zinsser, Plotz and Enders¹³ of a method for producing vaccine on a large scale. Cox and Bell¹⁴ have also developed a vaccine that is effective in protecting animals. These vaccines will undoubtedly be subjected to clinical trial, and the results will be awaited with interest.

The development of antiserum against rickettsial diseases continues to attract attention, and progress has been reported by Topping.¹⁵ It is quite possible that the use of large amounts of antiserum in the treatment of these diseases will definitely reduce the fatality rate.

It is becoming increasingly clear that typhus and Rocky Mountain spotted fever are present in various parts of the United States. Welch and Jakmaul¹⁶ and Campbell and Ketchum¹⁷ have reported cases of Rocky Mountain spotted fever in New England, and cases are now recognized along the eastern seaboard with increasing frequency. Campbell and Ketchum pointed out that there are no essential clinical differences between the Eastern and the Western varieties of Rocky Mountain spotted fever, and Topping and Dyer¹⁸ have isolated the Western strain in the eastern part of the United States, so that it would be advisable to classify cases on the basis of virulence or of behavior in guinea pigs rather than according to geographic and clinical type.

Typhus or Rocky Mountain spotted fever should be suspected in any patient who has the symptoms and signs of an acute infection with a skin eruption, especially if there are symptoms and signs referable to the brain and meninges, and congestion of the conjunctivas. If one remembers that rickettsial diseases caused widespread damage and lesions of the capillaries, especially of the brain, meninges and skin, and in this way cause anatomic damage, it is much easier to understand the symptoms and signs. All patients suspected of having either disease should be questioned for the possibility of tick bites, or at least contact with ticks. The Weil-Felix test, which becomes positive between the eleventh and nineteenth days, usually establishes the diagnosis.

American Q Fever

The recent studies of Hornibrook and Nelson¹⁹ and Dyer, Topping and Bengtson²⁰ of an outbreak of pneumonitis, which was identified as being due

to the rickettsia of American Q fever, are among the most interesting and valuable contributions to the study of infectious diseases this year.

During the last five years, there has been an increasing interest in a group of infections characterized by bronchopneumonia of indeterminate duration, and various other clinical features such as skin eruption, pericarditis, hematuria, enlargement of the liver, spleen and lymph nodes, jaundice, migratory arthritis and encephalitis. Excellent clinical descriptions of this disease are available in the papers of Murray,²¹ Kneeland and Smetana,²² Longcope²³ and Reimann.²⁴ Efforts have been made to isolate a virus or other infective agents from the blood and exudates of these cases without conclusive results. For this reason the recent report¹⁹ of the finding of rickettsia among a group of 15 patients with pneumonitis has excited widespread interest. The epidemic occurred among workers in one building of the National Institute of Health in Washington in the spring of 1940. The rickettsia of Q fever was isolated from 3 of these cases, in 2 from the blood and in 1, which was fatal, from the spleen. From the epidemiologic studies there was no convincing evidence that either personal contact or the intervention of an insect vector was responsible for the transmission of the disease.

These observations should serve as a stimulus for further investigation of cases of pneumonitis in other parts of the country to determine whether the same agent is responsible for the disease elsewhere.

WEIL'S DISEASE

Cases of Weil's disease are being recognized with increasing frequency in the United States,

England by Jeghers, Houghton and Foley,²⁶ and Proger²⁷ has observed a case in his own practice.

The recognition of Weil's disease depends on the isolation of the *Leptospira icterohaemorrhagiae* from the blood or urine of the patient by means of inoculation of susceptible animals and on the appearance of specific agglutinins in the blood plasma. The first step in the diagnosis, however, is to consider the possibility in cases of obscure infection with or without jaundice, especially if there is an associated severe myalgia, nephritis, hemorrhages into the skin, conjunctivitis or aseptic meningitis. Such a possibility becomes strengthened if the patient is a sewer worker, fish-handler, slaughterhouse worker or miner, is known to have been swimming in stagnant or polluted water or has lived or worked in rat-infested premises. Persons who fall into the canals of Holland frequently develop the disease.

The clinical features of Weil's disease vary widely, depending on the severity of the infection; for purposes of description they may be divided into three stages, although some patients may not show any of the features characteristic of the second and third stages. The first stage is characterized by the sudden onset of all the symptoms of an acute infection, — fever, chills, nausea, vomiting, pain in the muscles, especially of the calves, conjunctivitis and herpes, — with leukocytosis. In a few patients all the signs of meningitis appear.²⁸ If the patient recovers within a few days after the onset of the illness, and does not develop jaundice, the diagnosis may never be established unless the possibility of the disease is considered and agglutination tests are carried out.

About half the cases go on to the second stage, in which jaundice appears and may be intense

TABLE 1. Summary of Clinical and Laboratory Findings in Various Stages of Weil's Disease.

FINDINGS	INCUBATION PERIOD (4-19 DAYS)	FIRST STAGE (4-7 DAYS)	SECOND STAGE (7-10 DAYS)	THIRD STAGE (10-21 DAYS)
Clinical	None	Fever, chills, muscle pains, nausea and vomiting, meningeal signs, conjunctivitis, herpes labialis hemorrhagica	Jaundice (50 per cent), enlarged liver, hemorrhages and signs of nephritis (commonest in patients with jaundice)	Fever,* nephritis
Laboratory	None	Leukocytosis (rarely above 20,000), spirochetes in blood and urine	Leukocytosis, icterus, nitrogen retention, spirochetes absent from blood but present in urine, antibodies present in blood	Spirochetes absent in blood and urine, antibodies present in blood

*The fever in 25 to 40 per cent of cases lasts 4 to 20 days.

and Blake²⁵ has recently reviewed the salient features of the disorder and collected all the reported cases. The case reported by Blake himself occurred in a dairyman who about ten days before the onset of the illness had been engaged in demolishing an old barn, which was infested with rats. Other cases have been reported in New

and associated with hemorrhages into the skin and from the mucous membranes of the nose and gastrointestinal tract; there may also be hematomas. The third stage, which frequently appears within the third week, is characterized by fever and, in some cases, nephritis. The various stages and the clinical course are shown in Table 1.

TULAREMIA

Tularemia is a rare disease in New England, only occasional cases having been reported. Badger²⁹ reported 1 case of the typhoidal form of the disease, and McKinn³⁰ observed 1. During the past year, Belding³¹ has isolated *Pasteurella tularensis* from the organs of a rabbit in Massachusetts. Accordingly, physicians should be on the lookout for clinical cases of tularemia, especially during the hunting season. An excellent review of tularemia has been made by Foshay³² during the past year, and this should be read in detail by those who are interested in the disease. A few of the salient features of the disease may be summarized as follows:

Tularemia, which is caused by infection with *Past. tularensis*, is usually acquired in human beings by contact with infected rabbits, squirrels, ticks or biting flies (deer flies). Other less common sources of infection are cat bites, and contact with dressed chickens that have become contaminated through handling by poultrymen who handle infected rabbits. Other animals that may serve as a source of infection for man are quail, opossum, pheasant, grouse, skunk, beaver and snapping turtle. Rare cases occur from personal contact or from handling infected pelts of rabbits. Laboratory infections have been noted, and eating infected, insufficiently cooked food is also a source.

The diagnosis of tularemia is made by isolating the organism from the circulating blood or foci of infection, or by detecting specific agglutinins in the blood plasma. The clinical features that naturally suggest the nature of the disease are the constitutional symptoms and signs of infection, a local ulcerative (primary) lesion with satellite lymphadenopathy, usually of the skin of the upper extremities, face or conjunctiva (92 per cent), and the presence of metastatic lesions in the lungs and pleura (20 per cent). In 8 per cent of reported cases prolonged fever without local signs is the outstanding feature of the illness.

A typical history is as follows. After the dressing of a rabbit during the hunting season, the skin of the fingers is accidentally broken. For several days, usually two to five but varying from one to ten, there are no local or general signs of infection. Then there is a sudden departure from health, with fever and all the accompanying signs of infection.

At the site of the original injury an ulcerative lesion develops in about two thirds of the cases and attracts the attention of the patient and his physician. There is an associated enlargement of the regional lymph nodes. In the remaining third, the lymph nodes in the neighborhood of the orig-

inal injury are first noticed to be enlarged. Visible lymphangitis is not common unless the infection is a mixed one. Nodular lymphangitis may be present in a few cases. Usually the primary lesion appears with the onset of the fever, but it may not develop for forty-eight hours after the onset. In some cases there is an initial bout of fever lasting from one to four days, which is followed by a remission of from one to five days, after which time the fever becomes elevated for a period ranging between two and four weeks. During this febrile period, signs of metastatic lesions in the lungs, liver, spleen or other organs may appear, so that the patient may develop the signs of pneumonia, pleural effusion, pyo-pneumothorax, pericarditis or enlargement of the liver or spleen, with or without jaundice.

In about half the cases, the lymph nodes suppurate, and they may break down as long as five months after the onset of the disease. Recurrent enlargement of the lymph nodes may occur as late as three months to three years after the initial infection. In the recurrent swellings of the lymph nodes, suppuration occurs in about half the cases, and the pus is commonly sterile.

Relapses may occur from eight months to two years after the onset of infection. The average duration of the infection is about four months. Local lesions last on an average about thirty days.

Death occurs in 6 to 10 per cent of cases. It is seen oftenest in patients over fifty years of age and in those with the septicemic form of the disease, or in persons with other debilitating diseases.

From the review and study of Foshay,³² there is convincing evidence that serum treatment shortens the course of the disease. Serum must be given early and in adequate amounts (30 to 180 cc). The evidence that chemotherapy shortens the course of the disease is still controversial.

Agglutination tests are the most reliable diagnostic tests. They usually become positive after the first ten days of the disease, but in some cases on record positive tests appeared as late as the fourth week. Once they appear, they are present for years.

Positive intradermal tests with the especially prepared antigens (organisms oxidized with nitrous acid) are commonly observed in the first week of the illness, before the agglutination tests become positive.

BRUCELLOSIS

In 1939, the second edition of Huddleson's³³ excellent monograph, *Brucellosis in Man and Animals*, was published. This is the most important

discussion of the subject in English during the last few years. Since 1924, this disease has been recognized in various parts of the United States with increasing frequency. Most physicians are familiar with its widespread existence, and attempts are being made to establish the diagnosis in all cases of prolonged unexplained fever.

The isolation of *Brucella abortus* from the circulating blood or from a localized area of suppuration establishes the diagnosis of brucellosis or undulant fever. In many cases, however, such isolation is impossible and it is necessary to rely on the clinical course of the disease, the agglutination reaction, skin tests and the opsonic index of the circulating polymorphonuclear leukocytes.

So far as is known, the infection arises oftenest from the ingestion of organisms with food. They gain entrance to the body through the gastrointestinal tract, and indirect evidence leads one to believe that they focalize in the liver, spleen, lymph nodes and other organs, where they may, in rare cases, set up areas of suppuration. Generally speaking, however, they do not produce abscesses, but local physical signs due to suppuration are by no means unknown. Areas of infection have been found in the bones and joints,—especially the spine and larger joints,—the meninges, the endocardium, the periosteum, the liver and spleen, the ovaries, the genitourinary tract and the blood vessels.

The infection usually occurs in persons who consume raw milk from infected cows, and in persons who handle infected material coming from cows, goats or pigs. Butchers, slaughterhouse men, farmers and veterinarians frequently have the disease in a latent form.

When the infective organisms are not isolated from the circulating blood or local areas of infection, the diagnosis may be suggested in a patient with low-grade or high, irregular fever, with moderate splenomegaly, without localizing signs of infection, with a normal or slightly increased leukocyte count and with an increase in the lymphocytes and mononuclear cells. In these cases, to establish a diagnosis one must use the other laboratory tests, the most useful of which is the agglutination reaction. An increase in the titer above 1:40, especially when the increase occurs as the disease advances, is of diagnostic significance. When the blood cultures and agglutination tests are negative, the use of the skin tests and the opsonic index may provide valuable indirect evidence of infection. A positive skin test may be present without a positive agglutination reaction, or with a negative opsonic index. This may be taken as an indication of hypersensitiveness to the

products of *Br. abortus*, and it must be interpreted in the same way as a tuberculin reaction; that is, the positive test may indicate a previous or a present infection. When there is a positive opsonic index and a positive skin test in a patient with fever but without a positive blood culture or agglutination reaction, these tests have less diagnostic significance, since they indicate that the patient has developed sufficient antibodies in the past to allow phagocytosis of organisms and to show a reaction to the products of *Br. abortus* when injected into the skin.

Summing up these tests, it may be said that a positive blood culture is the most valuable. The agglutination test ranks second. A positive skin test with a negative opsonic index comes third. A positive skin test and opsonic index, without other evidence of infection by this group of organisms, is of little positive value in the diagnosis.

Since this infection tends to focalize in certain areas, the patient may come under observation with symptoms and signs of a focal infection, or once the diagnosis has been established, these focal infections may appear. The following clinical manifestations may suggest undulant fever: relapsing or undulating fever, which may be low grade or continuous with negative blood cultures, a moderate splenomegaly and a normal leukocyte count with an increase of the lymphocytes and monocytes; an infective spondylitis; an intermittent hydrarthrosis; a suppurative arthritis; an enlargement of the liver and spleen, with hematemesis; pelvic abscess; an abscess of the periosteum; an endocarditis; infective mycotic aneurysm of a large artery; a low-grade meningitis.

On the whole, the treatment of brucellosis is unsatisfactory. Chemotherapy with the various sulfonamide drugs has yielded results that are in many ways difficult to assess. A review of the effects, by Blumgart and Gilligan,³⁴ indicates that sulfanilamide has occasionally been effective. In many cases, however, the results are disappointing, since relapses are observed following an apparent remission induced by the drug. It is fair to say that no chemotherapeutic agent so far developed will be effective in all cases. Wainwright³⁵ has reported favorable results in some cases following the use of neoarsphenamine.

One form of treatment that has been used extensively is the injection of brucellin. The results in 100 cases have been summarized by Huddleson,³³ whose conservative statements warrant most careful consideration. He states that from his experience there is no doubt that the course of the disease may be shortened, provided certain procedures are followed and an adequate amount

of material is used. According to Huddleson, the course of the disease is altered "by producing a systemic allergic reaction which in turn is accompanied by a neutrophilic leukocytosis and increase in immune opsonins." It is also his opinion that the efficiency of brucellin depends on the existence and continuation of a state of sensitization in the patient under treatment. The absence of a state of sensitization at the beginning of treatment or its disappearance during treatment will be followed by poor results following the use of brucellin. It is for these reasons that the dose must be varied from one patient to another. Those who are interested in this method of treatment should consult Huddleson's monograph.

CASE 27061

PRESENTATION OF CASE

A fifty-year-old housewife entered the hospital complaining of hematemesis.

Approximately a year and a half before entry the patient developed a vague sense of epigastric pressure unaccompanied by other symptoms and relieved by a slight adjustment of her corset in the form of padding at the upper edge. Three months before admission, over a period of several weeks, she noticed that food sometimes seemed to "catch" in her throat. There was no pain, and with a drink of water the food passed on. No other symptoms appeared until one night, six weeks before entry, the patient awoke feeling as though she were "floating on air." In addition, she felt nauseated and suddenly vomited about one pint of bright-red blood. This incident did not recur, but since then she had suffered from slight anorexia, weakness, easy fatigability, and shortness of breath on exertion. Her stools were black for four weeks thereafter. Following the hematemesis, her physician instituted a dietary regimen of milk and cream for two weeks, then strained vegetables and riced foods, with a bismuth powder after each meal. The patient had not lost weight. At no time did she have postprandial pain, dyspepsia, colic, constipation, diarrhea, jaundice, food intolerance or swelling of the abdomen or legs. There was no history of excessive alcoholic consumption.

The patient had had pertussis at forty, and twelve years before admission a "broken-down gland" in the right posterior neck, which was drained and healed readily. The family history was noncontributory.

On examination the patient was well developed and well nourished and in no apparent distress. Examination of the heart and lungs was negative; the blood pressure was 118 systolic, 80 diastolic. The abdomen was tender in the mid-epigastrium. Vaginal examination showed a parous introitus and leukorrhea. The cervix was large and badly lacerated with marked erosions. The uterus was retroverted; the fundus was not felt, and the vaults were clear. Rectal examination was negative.

The temperature, pulse and respirations were normal.

Examination of the urine was negative. Examination of the blood showed a red-cell count of 4,500,000 with a hemoglobin of 55 per cent, and a white-cell count of 7600 of which 53 per cent were polymorphonuclears. A blood Hinton test was negative.

The nonprotein nitrogen of the blood serum was 21 mg. per 100 cc., the chlorides 108.1 milliequiv. per liter and the serum protein 6.0 gm. per 100 cc. The vitamin C level was 1 to 2 mg. per 100 cc. A gastric analysis showed 20 cc. N/10 free hydrochloric acid, with a total acidity of 37 cc. after injection of histamine. Examination of the stools was negative.

A gastrointestinal series showed a 7.5-by-5-cm. mass arising from a broad base on the lesser curvature and posterior wall of the fundus of the stomach. The base of the tumor lay just posterior to the cardia. The surface of the mass was rather smooth, but slightly lobulated, and one deep crater-like depression was seen in its lateral portion. There was only a slight shift in the position of the mass when the patient was upright. The rest of the stomach showed no evidence of disease.

The patient was given vitamins and a 600-cc. blood transfusion. On the fifth hospital day a gastroscopic examination was performed. The instrument passed readily into the cardia; there was no evidence of disease in the esophagus, and the cardiac orifice appeared normal. The instrument was then passed a few centimeters inside the cardiac orifice, where a smooth gastric mucosa without normal gastric rugae was seen. It was not possible to be sure whether this was normal gastric mucosa or neoplasm, and hence no biopsy was taken. There was a small amount of bleeding, and because of this, gastroscopy with the flexible tube was postponed. The following day this procedure was repeated. The pylorus was well visualized and appeared normal, as did the antrum; peristalsis was normal. In the upper part of the body in the five o'clock position there was a smooth, rounded, elongated submucosal tumor that appeared to be approximately 5 by 7 cm. in diameter and elevated 1 to 1.5 cm. above the surrounding mucosa. There was no visible break in the mucosa overlying the tumor. Near its base the rugae started to pass over the tumor, but were gradually flattened out. The mucosa surrounding the lesion was markedly atrophic, with clearly visible vessels shining through. The tumor appeared to extend to within 1 cm. of the cardia without involving it. Another 600-cc. blood transfusion was given, and on the fourteenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: In some ways I hesitate to have Dr. Holmes show us these x-ray films, because if the films bear out the description we have here in the text it brings the diagnosis down to one type of lesion. However, we shall see how difficult he can make it by his interpretation of the films.

DR. GEORGE W. HOLMES: The surprising thing is that some films show practically nothing abnormal and others show a very definite lesion. I presume that the latter present the correct picture, and I shall interpret them about as described in the record. There is a large smooth lobular mass in the fundus of the stomach with a well-defined crater in its center, a picture characteristic of one particular tumor. I suppose it is the same one you have in mind.

DR. ALLEN: Dr. Edward B. Benedict's description of this tumor confirms Dr. Holmes's interpretation.

We have, then, a patient with massive hemorrhage from the upper gastrointestinal tract.¹ According to the records in this hospital, this must fall into one of eight categories. The commoner causes of sudden massive hemorrhage are posterior-wall duodenal ulcer, gastric ulcer, gastrojejunal ulcer, esophageal varices, carcinoma of the stomach, hypertrophic gastritis, polyposis and leiomyoma. In this case we can rule out many of these lesions. We have no reason whatever to suspect the duodenum. We have no reason to suspect that this hemorrhage came from esophageal varices. The gastroscopist did not find gastritis. I do not believe that this is polyposis, because usually the polyps are multiple and do not show such a broad base as this tumor appears to have.

We do have to consider certain possibilities other than what I believe to be the obvious diagnosis. One cannot always be sure that a tumor, however smooth, however apparently submucosal, is not carcinomatous. Carcinomatous tumors are nearly always ulcerated, or if not ulcerated, they involve a much larger portion of the stomach than this one does. It is noteworthy that this tumor does not have a large ulcer crater, despite the presence of free hydrochloric acid in the stomach. We have recently reviewed all the gastric ulcers treated here in the past ten years and were much surprised to find what a high incidence of cancer there was in these patients beyond middle life, with a short story of indigestion. A person beyond middle life who has a gastric lesion with a short history has five times as much chance to have cancer as ulcer. We treat too many gastric ulcers conservatively, and let them get away

from us only to return in an inoperable state with obvious cancer. I think we can rule out such a possibility in this particular patient.

The tumors that are submucosal and that have a smooth surface as demonstrated both by x-ray and gastroscopy are apt to belong to the leiomyoma group. The majority of the patients who enter this hospital with leiomyoma of the stomach enter with massive hemorrhage, and most of them have a preliminary diagnosis of inoperable cancer when they get here. This location is not an uncommon one for leiomyoma. Two of the cases I have done have been so near the cardia on the posterior wall that to get them out without total gastrectomy the operation had to be done through an opening in the anterior wall of the stomach. Others have been found in various locations in the stomach, and the majority have been treated by partial gastrectomy. If one knew which of these tumors were benign, and a certain percentage of them seem to be entirely benign, one might get away with a local excision. In one of my cases that I did through the stomach, a smaller tumor than this one, the patient is alive and well after six years, with no evidence of recurrence. Another patient died four years after operation with jaundice and a palpable liver, so that although there was no autopsy confirmation, it is fair to assume recurrence. Quite a large percentage of them are malignant. They show sarcomatous degeneration and are usually termed leiomyosarcomas. Recently Ransom,² of the University of Michigan, reported on tumors of neurogenic origin in the abdomen, and about 8 of the 20 cases presented tumors of the stomach that looked grossly very much like the one that we are discussing today. Coller³ in discussing Ransom's paper called attention to the fact that if the histology of these tumors were more carefully reviewed more of them would be found to be of neurogenic origin.

The ulcer crater in the center of this smooth round tumor is characteristic of both the leiomyomatous and the neurogenic tumors. If one gets the specimen out one finds that the crater leads directly into a large blood vessel from which the hemorrhage comes.

One should mention the possibility of lymphoma in dealing with any intra-abdominal tumor, particularly one that is tender. So far as I know, I have not had the experience of seeing a lymphomatous lesion of the stomach that was admitted on account of massive hematemesis. In going over our ulcerative gastric lesions in the past ten years, we found only one benign tumor arising from the fundus of the stomach, and that was due to syphilis. This woman had a negative Hinton test, and nothing else about this case sug-

gests syphilis. Therefore, I shall make a diagnosis of leiomyoma of the stomach, possibly with sarcomatous degeneration, possibly a tumor of neurogenic origin.

DR. TRACY B. MALLORY: Are there any other suggestions? Dr. Homans, should you care to comment?

DR. JOHN HOMANS: No.

DR. MALLORY: Dr. Homans had a case very much like this some years ago that I remember reviewing. I was at that time interested in leiomyomas of the stomach, and a case at the Peter Bent Brigham Hospital was called to my attention. It seemed to me at first glance to be very typical, but Dr. Homans made a remark which I have not forgotten and which has influenced my thinking about these tumors ever since. He said, "I should be very cautious about accepting that as a leiomyoma, because she came back four years later with an intraspinal tumor, which Dr. Cushing removed. You had better be sure it is not a neurogenic fibrosarcoma."

DR. HOMANS: I remember the patient.

CLINICAL DIAGNOSIS

Leiomyoma of stomach.

DR. ALLEN'S DIAGNOSIS

Leiomyoma of stomach, with possible sarcomatous degeneration?

Neurogenic fibrosarcoma of stomach?

ANATOMIC DIAGNOSIS

Neurogenic fibrosarcoma of the stomach.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This patient was operated on by Dr. Edward D. Churchill; I am sorry he is not here to describe his operation. Because of the very high location, he decided to approach the tumor through the transpleural route. That was done, and it was found that the tumor was in the fundus, far enough separated from the mouth of the esophagus to do a fundusectomy, close up the stomach and leave it in continuity with the esophagus. The patient made a very successful recovery and was discharged on the sixteenth postoperative day, completely relieved. The tumor was of about the size described in the x-ray reports and did show central ulceration. In contrast to a leiomyoma, which after all is nothing but a fibroid, this tumor was quite soft, and appeared very edematous and vascular. On microscopic examination it is evident that it is a spindle-cell sarcoma growing at a moderate rate of speed, with fairly numerous mitotic figures, but no multi-

nucleated giant cells or other evidence of a high degree of malignancy. Further diagnosis of the tumor rests on the minute histologic character, and I am not sure if it were shown to a group of pathologists that they would give a unanimous opinion. I should classify it as a neurogenic fibrosarcoma, not as a leiomyosarcoma. In sections stained with phosphotungstic acid the normal muscle of the stomach wall showed good myoglia fibrils, whereas I could demonstrate none in the tumor cells.

I wonder, Dr. Allen, if it would have been possible to have handled this case as satisfactorily with an approach from below.

DR. ALLEN: Being an abdominal surgeon I should have taken it out from below. I think that a shoemaker must stick to his last. We saw a case this morning on grand rounds, a carcinoma of the stomach involving, we thought, the lower end of the esophagus, and I suggested to Dr. Churchill that it would be a good case to do transthoracically, whereupon he said, "Well for the sake of argument, why not approach it from the abdomen?" Either approach is satisfactory.

CASE 27062

PRESENTATION OF CASE

A sixty-year-old man entered the hospital complaining of bronchitis and fatigue of eight years' duration.

The patient stated that for twenty years he had suffered from chronic constipation with gaseous eructations after meals and for the eight years before entry from bronchitis occurring each winter, with a daily production of half a cupful of greenish-yellow sputum. In addition, for the previous three years he had noticed anorexia, weakness, easy fatigability and lack of energy as well as moderate dyspnea on exertion and slight orthopnea, but no edema or paroxysmal nocturnal dyspnea. Six weeks before admission he suffered an attack of "bronchitis" with slight fever, and a mild cough with a small amount of sputum. Since then he had noticed that his sputum was blood streaked. Two weeks before admission the patient had a chill with fever, and developed a pain in his left chest. He went to bed, weak and exhausted with generalized aching, and complained of dyspnea, an increase in coughing and bloody sputum. There was no palpitation, peripheral

edema or weight loss, but he had a few night sweats. Furthermore, he complained of difficulty in starting urination, with dribbling and nocturia once or twice a night for an unstated period. At the time of admission he was raising small amounts of bloody, apparently purulent sputum.

On examination the patient was well developed and well nourished, lethargic, extremely uncooperative, flushed, slightly cyanotic and apparently ill. The brachial and temporal arteries were tortuous. The heart was moderately enlarged to the left, with a hifid apical impulse. The sounds were rapid and of poor quality with a presystolic gallop rhythm; the blood pressure was 138 systolic, 80 diastolic. Examination of the lungs revealed slight dullness to percussion at both bases; the diaphragmatic excursion was normal. There were many coarse crackling rales in the left axilla, and anteriorly and posteriorly at the left base. A few rales were heard at the right base. Examination of the abdomen was negative except for an easily reducible right inguinal hernia in the scrotum. The prostate was enlarged, smooth, soft and tender. Examination of the nervous system was negative.

The temperature was 101°F., the pulse 100, and the respirations 30.

Examination of the urine showed a ++ test for albumin. Examination of the blood showed a red-cell count of 5,060,000 with a hemoglobin of 100 per cent, and a white-cell count of 13,800 with 82 per cent polymorphonuclears. A blood Hinton test was negative. A gastric analysis gave a total fasting level of 2 cc. of N/10 hydrochloric acid per 100 cc., and a level of 6 cc. half an hour after the injection of histamine; there was no free acid, and a guaiac test was negative. The vital capacity of the lungs was 2000 cc. Examination of the stools was negative.

X-ray films of the chest showed a small amount of fluid in the left pleural cavity. The space between the gas bubble in the stomach and the diaphragm was unusually large, and there was a slight irregularity of the fundus of the stomach. The lung fields on both sides contained a number of rather poorly defined, approximately round areas of increased density measuring up to 2 cm. The heart was markedly increased in size, particularly to the left. The aorta was tortuous and slightly dilated.

A gastrointestinal series showed the esophagus to be normal. The deformity of the fundus previously described was seen to be produced by downward displacement of the fundus and not by intrinsic disease of the stomach. The downward displacement was apparently due to a slightly en-

larged spleen. There was no evidence of intrinsic disease of the upper gastrointestinal tract.

An electrocardiographic recording showed normal rhythm at 105, a PR interval of 0.18 second and a prominent P₂. The QRS complex was widened up to 0.08 second, with slurring and splintering. There was slight depression of ST₁ and ST₂, and elevation of ST₃ and ST₄. T₁ was slightly inverted, T₂ low.

The patient was given digitalis and one 2-cc. dose of mercupurin and appeared to improve satisfactorily, becoming more alert and co-operative. Four days after admission the temperature dropped to normal, the white-cell count to 10,000. X-ray examination of the chest showed the lesions to be slightly smaller than at the last examination. There was still a small amount of fluid in the left pleural cavity, and the heart was still enlarged, though slightly smaller. On the seventh hospital day marked tenderness was noticed in the left calf, with cordlike masses suggestive of thrombosed veins. Two days later the dullness and rales at the left lung base had disappeared, but the heart rate still averaged 100. Later that day the patient was found dead in bed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD F. BLAND: I suspect several pathologic conditions were found in this patient, but I think that the principal diagnosis involves an explanation for the cough, sputum, hemoptysis and sudden exitus. He was sixty years old, had had so-called "winter bronchitis" for a number of years, and had raised a fair amount of sputum. I assume that this annual winter bronchitis represented a low-grade pulmonary infection, with perhaps slight structural alterations in the bronchial tree. In addition, in view of what comes later, perhaps there had also been an element of circulatory weakness. The evidence—marked cardiac enlargement, a gallop rhythm indicating serious weakness and an abnormal electrocardiogram—seems to show clearly that on admission he had significant cardiac disease. There is nothing, however, in the story that particularly suggests a recent acute change in the heart. Furthermore, the patient appeared to improve on digitalis. We must therefore assume that he had serious cardiac disease, presumably on a coronary basis. He had no known hypertension, and we can be reasonably certain that he did not have valvular disease. I think his heart may have been of some importance in the final events, but not the chief cause of his exitus. Finally, he had benign hyperplasia of the prostate, which appears not to have had much bearing on his final illness. So much for the background of his illness.

It seems to me that the central problem involves the final illness, and the findings in the lungs are probably most important. I wonder if we might see the x-ray films now. I take it that the gastrointestinal tract was examined with such zeal because of the original chest film, which showed the gas bubble in the stomach not quite so close to the diaphragm as it should be. Otherwise, I think one might have hesitated to pass a stomach tube into a patient as sick as he appeared to be.

DR. GEORGE W. HOLMES: The increase in the distance between the gas bubble and the diaphragm is not positive evidence of any pathologic lesion, but is worth taking note of. The complete absence of abnormality of the mucosal folds in the fundus rules out, I think, tumor in this part of the stomach. The widening of the space may be due to distortion of the picture, or as pointed out in the record, to enlargement of the spleen. The most obvious finding in the chest films is the enlargement of the heart. The enlargement is general, perhaps a little more to the left than to the right, and the border of the left ventricle is prominent. It was stated in the report that the aorta was somewhat dilated as well as tortuous. I think that the dilatation was very slight, if existent at all. I do not believe he had syphilitic aortitis, or the marked dilatation we sometimes see with hypertension. The description of the lungs is a little misleading, because it gives the impression that the lesions might have been due to metastatic cancer. To me they do not look that way. The general thickening of the lung markings throughout the chest and the haziness on the right side might have been due to pleuritis, but in general the picture looks more like localized atelectasis, pulmonary infarct, acute respiratory infection or something of that sort.

DR. BLAND: There is not much evidence of congestion?

DR. HOLMES: No; that is not the picture of congestive failure.

DR. BLAND: The mediastinum looks all right?

DR. HOLMES: Yes.

DR. BLAND: In general when a patient of this age comes in coughing and raising sputum, with fever and hemoptysis, one would like to know what the sputum shows microscopically, and I think we can assume that it was not remarkable, since nothing was said about it. Certainly the course of the illness does not suggest either tuberculosis or pneumonia. After seeing the x-ray films, I think we can discard tuberculosis. I considered cancer at some length from the written report of the x-ray studies, but after seeing the films I am

inclined to discard that without serious consideration because the patient was in fairly good general condition, certainly not emaciated. The red-cell count was not down, and the onset of the disease does not particularly suggest a malignant lesion of the lung, either primary or secondary. I suppose, as noted previously, that the gastrointestinal tract was investigated so carefully because of the suggestion in the first chest films, but there was certainly no indication of disease from later x-ray study of the gastrointestinal tract or from examination of the stools. The patient probably did not have a tumor of the lung, either carcinoma or lymphoma. One can occasionally get hemoptysis with lymphoma, but it is very rare. Metastatic carcinoma of the lungs can rarely cause hemoptysis, but hemoptysis in the presence of cancer suggests primary bronchiogenic carcinoma.

Finally, we come to a consideration of what I think seems most likely; namely, that he had, complicating his heart disease and perhaps his chronic mild bronchiectasis, multiple pulmonary emboli with infarction. From the written description of the films, it seemed to me that either cancer or infarction of the lungs might be present. After seeing the films, there can be little doubt about the infarction. There was a good background for it. There is clear evidence of serious heart disease and some circulatory weakness, as shown by the gallop rhythm. The patient had a mild infection, to begin with, a chill, which usually means infection, and probably took to bed, which favored the development of deep phlebitis. Toward the end of his illness, signs of superficial phlebitis appeared in the veins of the left calf. Then we come to the sudden exitus interrupting his apparent improvement. We are on uncertain ground when we attempt to interpret the exact cause of death. He had serious cardiac disease, and something abrupt may have happened in connection with the heart, for example, ventricular fibrillation. Dr. Mallory may not find an obvious cause. On the other hand, since we are dealing with recurring pulmonary infarcts and obvious disease of the veins in one leg, it is somewhat likelier that he had a terminal pulmonary embolus.

DR. WILLIAM B. BREED: It is interesting that just prior to death, as I remember, he had a marked diuresis due to mercurial diuretics, and I wonder whether you would take that into consideration.

DR. BLAND: We have seen one or two things happen occasionally, especially in patients getting full doses of digitalis, if a vigorous diuresis follows the use of mercurial diuretics. Such a diuresis sometimes increases the effect of the digitalis.

We have seen patients become mildly toxic from digitalis under such circumstances. I have seen one patient recently who developed a cerebral thrombosis the night following a vigorous diuresis. Whether that was chance or was caused by a concentration of the blood, I do not know.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease.
Mild congestive failure, with pulmonary congestion.
Pulmonary embolism.
Bronchiectasis?
Carcinoma of lung?

DR. BLAND'S DIAGNOSES

Recurring pulmonary emboli.
Pulmonary infarction (multiple).
Coronary heart disease.
Phlebitis, left leg.
Bronchiectasis, mild.
Prostatic hypertrophy.

ANATOMIC DIAGNOSES

Coronary thrombosis, old and recent.
Myocardial infarction, old.
Mural thrombus, left ventricular.
Arteriosclerosis, coronary, aortic and generalized, severe.
Pulmonary infarcts, multiple.
Pericarditis, chronic, fibrous.
Rheumatic heart disease, aortic valvulitis, slight.
Infarcts of spleen.
Thrombosis of popliteal vein, left.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The post-mortem examination showed multiple pulmonary infarcts, most of them recent, although one showed evidence of organization and must have been present for a few weeks before death. The immediate

mechanism of death was not a massive pulmonary embolus. The heart was very markedly hypertrophied—575 gm. The left ventricle was much dilated as well as hypertrophied, and its entire apex consisted of a fibrous scar, overlying which was a partially organized thrombus. All the coronary arteries were markedly sclerotic, and the lumens reduced merely to slits. The main branch of the right coronary artery was completely occluded by an old organized thrombus, and the remaining portion showed a quite fresh thrombus, which I think was the immediate cause of death. There was no visible recent infarction in the heart. A very slight rheumatic deformity of the aortic valve was found, but was not, I believe, significant.

A PHYSICIAN: Had there been any story of angina?

DR. MALLORY: No.

DR. DONALD S. KING: Was there a chronic bronchitis?

DR. MALLORY: Not of significant grade.

DR. HOLMES: Do you think the pronounced curve in the left ventricle was due to aneurysm?

DR. MALLORY: We did not classify this as an aneurysm of the heart, although there was certainly localized dilatation.

DR. BLAND: May I ask Dr. King a question? I am uncertain what they meant by "winter bronchitis."

DR. KING: So was I. That is why I asked the question.

DR. MALLORY: I can say that there was no chronic bronchiectasis, and a little inflammatory infiltration in the bronchial walls is so usual that we do not pay much attention to it.

DR. KING: What about the spleen?

DR. MALLORY: It was somewhat enlarged. There was a localized infarct of the upper pole, definitely adherent to the diaphragm, which I think could have resulted in pressure on the fundus of the stomach.

CHEMOTHERAPY AND SEROOTHERAPY OF PNEUMONIA

THE season for severe respiratory infections has arrived, and the number of pneumonia cases is soon expected to reach its peak. Physicians are fortunate in having available powerful weapons with which to combat this highly fatal disease. Properly used, they are expected greatly to reduce the number of deaths from pneumonia.

The first line of therapeutic attack will be through the use of chemicals. During the present season this will mean either sulfapyridine or sulfathiazole. It has been difficult to judge which of these two drugs is superior. Each has its favorable and its unfavorable features. These have been summarized in a recent review* in the

*Finland, M. Treatment of pneumonia. *New Eng. J. Med.* 223:499-506, 1940.

Journal. In general, because sulfathiazole produces nausea and vomiting less frequently and of less severity, it will probably be the drug of choice, particularly when patients are treated in the home. The mortality rate in cases treated with sulfathiazole, according to available published reports, is about the same as that in cases treated with sulfapyridine. Two points concerning the use of drugs in the treatment of pneumonia are worth repeating. The first is that sulfanilamide should not be used in the treatment of cases of acute pulmonary infection unless the infection is known to be due to a hemolytic streptococcus, and then only if sulfapyridine in adequate doses is not well tolerated. In the second place, failures from chemotherapy are to be expected, and under such conditions, changing from sulfapyridine to sulfathiazole, or vice versa, will probably not be successful except in those cases in which the change is made because of some toxic effect. Serum should be given in such cases, provided a specific type of pneumococcus is causing the infection.

In this issue of the *Journal* appears the reprint of a circular, issued by the Massachusetts Department of Public Health, concerning the use of sulfapyridine, sulfathiazole and specific serums in the treatment of pneumococcal pneumonias. When sulfapyridine was first introduced, many extreme views were expressed concerning the relative merits of drugs and serums. It is now recognized that both agents are effective and that they differ fundamentally in their mode of action. Almost all workers in the field of pneumonia therapy are now agreed that a certain proportion of cases of pneumococcal pneumonia fail to show adequate response to proper therapy with either sulfapyridine or sulfathiazole alone. Such failures in no wise alter the chances for success with antipneumococcus serums. Since serotherapy is highly specific, it is essential to be prepared for all contingencies by obtaining sputum for typing and blood for culture before treatment with drugs is undertaken. Chemotherapy need not be withheld until the results of these laboratory procedures become known, except in individual cases in which

there are definite contraindications for drug therapy. Fortunately, the latter are rare.

Early treatment with sulfapyridine or sulfathiazole offers the greatest hope for reducing the mortality from pneumonia and of bringing about rapid cures. Serum therapy is reserved for severe cases and for those in which drugs are contraindicated. In all such cases the greatest success from serotherapy is to be expected if the serum is administered early. It should also be used in all other cases due to specific types of pneumococci when, after a trial of from twenty-four to thirty-six hours, an adequately favorable response to chemotherapy has not been obtained.

The recommendations of the Massachusetts Department of Public Health in regard to the procedures to follow and the indications for drugs or for serums, or for the combination of chemotherapy and serotherapy, are a result of the summation of the experiences of a number of leading clinicians in this field. They are not absolute but are the best guide now available if one is to obtain optimum results.

The Department of Public Health is now distributing suitable containers for blood cultures. Physicians should avail themselves of this service, since pneumococcal typing is simplest and most reliable when positive blood cultures are used. Furthermore, the results of blood cultures offer the best guide for prognosis and for serum therapy. In addition, the Department of Public Health is furnishing serums for the treatment of all patients in whom positive blood cultures for specific pneumococcal types are obtained. All this should be adequate inducement to the physician for the slight additional effort required in taking such blood cultures. It should not, however, relieve him of the responsibility of seeing that sputum is properly collected and sent for typing as soon as possible after a clinical diagnosis of pneumonia is made or suspected.

CRIMINAL ASPECTS OF FAITH HEALING

To most citizens it is a novel idea that faith healing has criminal aspects, yet if one remembers

the saying of a distinguished historian that "liberty, next to religion, has been the motive for good deeds and a common pretext for crime," one should not be surprised that even the practice of faith healing may on occasion violate the law of the land. As the author of an article that appears elsewhere in this issue of the *Journal* points out, the government interferes, not with religious opinions, but with the acts of individuals, it discriminates among acts expressive of religious belief, no matter how logically or illogically they may be derived from the belief, and decides that some are in violation of the law and that others are not.

It is clearly within the rights of a community to protect itself from a communicable disease in any way approved by the best scientific opinion, whether by mere restraint or isolation or by specific treatment, according to the nature of the disease and the risk of transmission from the patient to other persons. If the disease is noncommunicable and occurs in an adult of sound mind, it is generally, if not always, agreed that it is for the patient to decide whether medical advice shall be sought, and if sought, whether it shall be followed. It is in the case of noncommunicable disease occurring in the legal "infant" that controversy has been most violent. Yet here also the decisions of the courts are clear: any person who has the custody of a child is under a duty to supply the "necessaries of life, medical attention . . . included."

One point about which the various statutes differ is the pertinence of compensation in establishing violation of the law. The more general view is that the compensation is mere proof of the fact that a service has been rendered, and that other evidence is required to determine whether it was a medical or some other service for which the fee was paid.

The number of citations of court opinion raises the question whether the magnitude of the danger demands a change in the statute. The problem is not to be attacked lightly, and the situation is one that should be explored thoroughly before a specific remedy is recommended. Just what the detailed facts are, no one knows, but

it is generally true that all persons who reject medical care because of religious scruples constitute, according to their number, a very grave peril to the health of the community. There are also the possibilities of much illness and many preventable deaths, which, where "infants" are concerned, the community certainly should prevent. If it does not know, it cannot act. The situation must remain serious, because in this field no competent and critical medical opinion is available. Is the true cause of death among those who are attended by faith healers ever known?

MEDICAL EPONYM

GHON TUBERCLE

In a monograph of 143 pages, Anton Ghon (1866-1936), professor of pathological anatomy at the German University in Prague, discussed *Der primäre Lungenherd bei der Tuberkulose der Kinder* [*The Primary Lung Focus in Childhood Tuberculosis*] (Berlin u. Wien, Urban u. Schwarzenberg, 1912). A portion of the translation follows:

My investigations go back to the year 1903. They originated without any knowledge of the work of Küss. . . . The results of my studies confirm the findings of Küss and H. Albrecht. They consequently contribute nothing essentially new.

We found primary lung foci in more than 75 per cent of our cases. . . . If . . . the number of primary lung infections should be reduced to even 90 per cent, they would still justify the conclusion that in the child, the primary infection of the lung is the usual form of tuberculous infection. Surely, this fact has great practical significance.

ACUTE RHEUMATIC FEVER DEVELOPING DURING PREGNANCY

Mrs. E. B., a twenty-eight-year-old para III, was admitted to the hospital on May 21, 1940, when she was five months' pregnant. She had been referred from the prenatal clinic with a history of

passage of "bloody urine" for two days, with associated pain on urination, and marked weakness and night sweats since the onset of pregnancy.

The family history was noncontributory. The patient's past history included measles, whooping cough and scarlet fever. She had undergone a tonsillectomy as a child, and an appendectomy had been performed on March 25, 1940. The first pregnancy terminated in a normal delivery at eight months. The second pregnancy was complicated by albuminuria and hypertension and terminated in a breech extraction. Catamenia began at the age of thirteen, were regular with a thirty-day cycle and lasted five to six days without discomfort. The last regular period began on December 22, 1939, making the expected date of confinement, September 30, 1940.

The patient was first seen in the prenatal clinic on May 15. Physical examination at that time showed a well-developed, poorly nourished woman. The weight was 106 pounds. The heart was not enlarged; there was a harsh systolic murmur over the mitral area, transmitted to the axilla, and a soft systolic murmur was heard at the pulmonic area, not transmitted. The lungs were clear and resonant; there were no rales. The blood pressure was 120 systolic, 70 diastolic.

On admission to the hospital the patient was seen in consultation by a urologist, who advised kidney-function tests, x-ray studies and cystoscopy. A urinalysis showed a specific gravity of 1.018, a trace of albumin and a large number of red blood cells and an occasional white blood cell per high-power field. Blood examination showed a white-cell count of 10,200, a red-cell count of 3,930,000 and a hemoglobin of 74 per cent. The blood nonprotein nitrogen was 26 mg. per 100 cc., the uric acid 4.8 mg.; a phenolsulfonephthalein test showed 50 per cent excretion the first hour and 10 per cent the second. Stereograms of the chest showed increased hilar infiltration in both lungs. The heart was normal in size and position. Retrograde pyelograms of the right kidney showed a moderate degree of dilatation of the upper calyces and ureter; there was no evidence of calculi. Bladder culture at the time of cystoscopy revealed a few gram-positive cocci; the right-kidney culture was sterile. Diagnoses of hydronephrosis and hydroureter were made.

The patient was placed on a high-vitamin, high-calorie diet, with liver and iron therapy. On May 27, one week after admission, the patient's temperature rose to 101°F., and she complained of a sore throat. Examination revealed uniform redness of the postpharyngeal wall. On the following day she complained of tenderness and stiffness of the left knee and ankle. On examination

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

there were redness, swelling, tenderness and limitation of motion of the left knee and ankle. A medical consultation was held, and the consultant's impression was that the patient had acute rheumatic fever with early endocarditis. She was placed on salicylate therapy. Repeated urinalyses continued to show a slight trace of albumin and a large number of white blood cells in the sediment. On May 29 the blood white-cell count was 9100, on June 7, 14,100, on June 20, 11,800, on July 3, 14,300, and on July 26, 7200.

The patient also complained of recurring bouts of uterine contractions. These were controlled with medication. The uterus had increased to a size consistent with the date of the last menstrual period, the fetal heart tones were of good quality.

She continued to run a temperature ranging from 98 to 101°F. Two weeks after the onset of infection the left wrist and elbow became similarly involved. On July 20 the temperature dropped to normal, and remained at that level until delivery. The acute inflammation of the joints subsided shortly thereafter, leaving only a stiffness of the left ankle joint.

During hospitalization there were no signs or symptoms of cardiac decompensation. The blood pressure was never higher than 120 systolic, 70 diastolic.

The patient started in active labor spontaneously on September 12 at 10 a.m. Analgesia consisted of 6 gr of Nembutal. At 1:30 p.m., under light ether anesthesia, she was delivered of a living male child, weighing 6 pounds, 10 ounces. The puerperium was uneventful, and the patient was discharged on October 5.

Examination of the heart at the time of discharge showed no enlargement by percussion or x-ray. There was no rub. The rhythm was regular, the rate 76. The sounds were of good quality. There was a soft systolic murmur at the apex, not transmitted. There were no other murmurs. The blood pressure was 110 systolic, 70 diastolic.

Comment. This is a very interesting case of acute rheumatic fever that developed during pregnancy. The treatment was extremely conservative, the patient remaining in the hospital from the onset until after delivery, which was normal. The evidence of heart disease was minimal, and there were no periods of decompensation. At last note the patient's heart was well compensated and showed no evidence of serious damage.

MEDICAL POSTGRADUATE EXTENSION COURSES

The following sessions, given by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, have been arranged for the week beginning February 9.

MIOOLESEX EAST

Tuesday, February 11, at 4:15 p.m. at the Melrose Hospital, Melrose. *Technic and Treatment of Primary, Secondary and Tertiary Syphilis.* Instructor: William P. Boardman. *Walter H. Flanders, Chairman.*

MIOOLESEX SOUTH

Tuesday, February 11, at 4:00 p.m., at the Cambridge Hospital, Mt. Auburn Street, Cambridge. *Chemotherapy in the Treatment of Gonococcal Infection.* Instructor: Oscar F. Cox. *Dudley Merrill, Chairman.*

NORFOLK

Thursday, February 13, at 8:30 p.m., at the Norwood Hospital, Norwood. *Recent Advances in Medical Therapeutics.* Instructor: Charles L. Short. *Hugo B. C. Riemer, Chairman.*

NORFOLK SOUTH

Monday, February 10, at 8:30 a.m., at the Quincy City Hospital, Quincy. *Pediatric Case Discussions.* Instructor: James M. Baty. *David L. Belding, Chairman.*

SUFFOLK

Thursday, February 13, at 4:30 p.m., in John Ware Hall, Boston Medical Library. *Acute Abdominal Pain.* Instructor: Stanley J. G. Nowak. *Reginald Fitz, Chairman.*

DEATHS

BUCKLEY—JAMES T. BUCKLEY, M.D., of Worcester, died January 24. He was in his sixty-fifth year. Dr. Buckley attended Williams College and received his degree from the Baltimore Medical College in 1902. He had been practicing in Worcester for over twenty years, and prior to that had practiced in Marlboro for about fifteen years.

He was a former member of the Massachusetts Medical Society and the American Medical Association.

His widow, two daughters and two sons survive him.

WEEKS—JOSHUA F. WEEKS, M.D., of New Bedford died January 12. He was in his seventy-fifth year.

Born in Dartmouth, he attended the University of the Green Mountains, Burlington, Vermont, and received his degree from the University of Vermont College of Medicine in 1890. He settled in New Bedford and began practice.

Dr. Weeks was a member of the Massachusetts Medical Society, the American Medical Association and the New Bedford Medical Society.

Two children survive him.

CORRESPONDENCE

TREATMENT OF PNEUMOCOCCAL PNEUMONIA

To the Editor: The Massachusetts Department of Public Health has recently revised its circular on the use of the specific drugs in the treatment of pneumonia. With this exception the pneumonia program of the department is the same as that of last year. The program includes:

The provision of concentrated therapeutic (horse) serums for Types 1, 2, 5, 7 and 8, obtainable for the treatment of patients with infections due to one of these types, as determined by an approved typing laboratory.

The provision of concentrated therapeutic (rabbit) serums for Types 4, 9, 14 and 18 on the basis indicated above.

The provision of concentrated therapeutic (rabbit) serums of all other types for patients with *bacteremia*, *meningitis* or *peritonitis* due to one of these types, the determination of which has been made by an approved typing laboratory.

A circular describing the use of sulfapyridine and sulfathiazole in treatment of pneumococcal pneumonia.

Revised case-report forms, supplied by the department, which must be completed and returned to the department for all serum-treated cases.

Receipt forms which must be signed by the physician receiving the serum and by the issuing agency.

The distribution of therapeutic horse serums will be continued as in previous years through typing laboratories. Therapeutic rabbit serums for Types 4, 9, 14 and 18 will be available through the five typing laboratories from which they were supplied last season. All other therapeutic rabbit serums will be available from only two points—the Bacteriological Laboratory at the State House, Boston, and the Westfield State Sanatorium at Westfield.

The rabbit serums are being purchased, and the amount of money available for this purpose may not suffice for all demands. Therefore, the continuation of this service will depend greatly on the conservation of funds effected through the prompt return of unused serum.

Copies of the new drug circular and the list of approved typing laboratories and serum stations are being mailed to all physicians in the State and are also available at the approved typing laboratories. Additional copies of the circular and the list of the laboratories at which the various serums may be obtained will be furnished by the department on request. They are reproduced below.

PAUL J. JAKMAUJ, M.D.,
Commissioner of Public Health.

State House,
Boston.

THE SULFONAMIDE DERIVATIVES, SULFAPYRIDINE AND SULFATHIAZOLE, IN THE TREATMENT OF PNEUMOCOCCAL PNEUMONIA

These drugs and antipneumococcal serum are of definite value in treating pneumococcal pneumonias. Sulfapyridine and sulfathiazole appear to be about equally effective and are superior to sulfanilamide. Sulfapyridine is superior to sulfathiazole in the treatment of pneumococcal meningitis.

1. Before starting treatment with drug or serum:

1. Obtain sputum for typing and blood for culture.

2. Make complete blood counts, including red and white cells, differential and hemoglobin determination.
3. Make complete urine examination; and, if indicated, blood nonprotein nitrogen determination.

(2 and 3, above, should be done daily while patient is receiving sulfapyridine or sulfathiazole in full doses, or if abnormalities are encountered; and every 2 to 3 days during entire period of drug administration.)

II. *General Considerations.* Because the drugs and the serum differ in their mode of action, neither is a complete substitute for the other. Sulfapyridine and sulfathiazole inhibit the multiplication of the pneumococcus, whereas specific serum furnishes additional antibodies which may be necessary for the destruction of the organisms. By combining drug and serum less of each may be needed than either would require alone. Unless one or the other is contraindicated, serum is recommended as a supplement to either sulfapyridine or sulfathiazole in the following situations:

1. Treatment is begun after the third day of the disease.
2. Patient is over 50 years old.
3. Patient is pregnant or in first week of puerperium.
4. Pneumococcus bacteremia is known to be present.
5. There is involvement of more than one lobe.
6. There is no obvious improvement within 18-24 hours after the initial dose of sulfapyridine or sulfathiazole; serum therapy may be delayed to 24-36 hours after the initial dose of the drug in the absence of 1-5 above.

III. *Contraindications to the Use of Sulfapyridine or Sulfathiazole.* Only under the most exceptional circumstances should sulfapyridine or sulfathiazole be given in the presence of either of the following conditions:

1. History of previous toxic reactions (anemia, agranulocytopenia, anuria, hematuria or hepatitis) to any of the *sulfonamide derivatives*.
2. Hemolytic anemia or granulocytopenia from any cause.

A difference of opinion exists as to the importance of previous drug rash, impaired kidney function or jaundice as a contraindication to sulfapyridine or sulfathiazole therapy; therefore the desirability of treating patients with these conditions is a matter of judgment. Great care must be exercised under these conditions, and the drug stopped at the first evidence that the functions are further impaired or if the drug rash recurs.

If a drug is to be given to postoperative patients, sulfathiazole is less likely than sulfapyridine to cause vomiting.

IV. *Dosage and Procedure of Treatment.* The rate and degree of absorption and excretion of sulfapyridine and sulfathiazole are variable, hence there can be no hard and fast rule of dosage. When oral administration is interfered with by vomiting or when it fails to give an adequate blood drug concentration,

*Approval pending, application made and evaluation of performance is in progress

†Specimens for typing accepted from S = staff members and hospital cases only, A = any physician; H = hospital cases only, M = any physician in municipality

Typings are done without charge at the State Bacteriological Laboratory, Boston. All other laboratories, except those maintained by municipalities, charge fees for typing. Special arrangements can be made for typings done on persons unable to pay when treated in the home.

resort may be had to the intravenous use of sodium sulfapyridine. Because of the danger of venous thrombosis and perivascular necrosis, the use of sodium sulfapyridine should be restricted to such cases. For details of its use, reference should be made to the manufacturers' circulars.

In general the following procedure for oral administration is at present recommended:

1. Dosage. (The drug is given orally and on schedule; the patient should be awakened if necessary to give drug.)

- a. Adults: 2 gm., followed in 4 hours with 1 or 2 gm., then 1 gm. every 4 hours until temperature, pulse and respiration are essentially normal for 48 hours; then 1 gm. every 6 hours for 2 to 3 days. From the standpoint of safety the drug should not be continued for longer than 96 hours unless daily blood drug-level determinations are being made.

- b. Infants and children: initial dose 0.25 gm. per 10 lb. body weight and maintenance dose 0.75 gm. per 10 lb. body weight per 24 hours administered in divided doses at 4 to 6-hour intervals.

- c. The giving of the drug in milk, fruit juice, gruel or applesauce may be helpful. For nausea, small doses of one of the milder sedatives or carminatives may be tried. It is well to remember that, with vomiting, there may be some loss of fluids and chlorides, as well as a loss of the drug, and infusions of saline subcutaneously or intravenously may be necessary to replace these losses.

2. Relapse or extension may occur if:

- a. The drug is discontinued too soon after a therapeutic response has been obtained, particularly in cases treated early in the course of the illness; or

- b. The pneumococcus causing the infection becomes resistant to the drug (sulfapyridine or sulfathiazole fast); if this occurs, further treatment with the drugs is of no avail and serum therapy is indicated.

3. The action of the drug may mask the symptoms of empyema or other surgical conditions, but does not lessen the need for surgical action in such conditions.

4. Blood drug-level estimations should be made after 12 to 18 hours of treatment and every 1 to 2 days thereafter; a level of 4 to 6 mg. of free drug per 100 cc. of blood is usually considered adequate, and a level of 15 mg. is probably the upper limit of safety.

V. Reactions from Sulfapyridine or Sulfathiazole.

1. Those reactions which require stopping the drug and, in some cases, active therapeutic measures are:

- a. Blood changes, which may include hemolytic (or other severe) anemia and granulocytopenia;

- b. Effects on the urinary system, which may include gross hematuria, ureteral pain,

urinary obstruction, nitrogen retention and nephritic edema;

- c. Toxic hepatitis, evidenced by jaundice.

2. Reactions which may require stopping the drug and institution of appropriate therapy are:

- a. Severe and persistent nausea and vomiting, particularly when associated with postoperative cases, loss of chlorides, etc. (See IV 1 c.);

- b. Drug fever, drug rashes; and

- c. Marked central-nervous-system disorders, including vertigo, headache and mental depression or excitement.

Reactions may be detected early or sometimes avoided if the precautions outlined in Sections 1, 2 and 3 and Section IV 4 are followed.

These recommendations have been approved by the Pneumonia Advisory Committee.

REPORT OF MEETING

WILLIAM HARVEY MEDICAL SOCIETY

A regular meeting of the William Harvey Medical Society of Tufts College Medical School was held at the Beth Israel Hospital on November 8, 1940, with Dr. William Dameshek presiding. Dr. Maxwell M. Wintrobe of Johns Hopkins Medical School spoke on "Experimental Studies on Pernicious Anemia, with Particular Reference to the Central-Nervous-System Manifestations."

In introduction the speaker reviewed the outstanding clinical, laboratory and historical data relative to pernicious anemia. The chief difficulty in the experimental production of the syndrome has been the inability consistently to produce in lower animals a picture similar to that of human beings. It has been found nearly impossible to devise an adequate diet lacking in extrinsic factor, and intrinsic factor has been demonstrated to exist in other parts of the gastrointestinal tract than the stomach.

Dr. Wintrobe's attack on the problem originated in the observation that the number of erythrocytes increases and the size decreases as one ascends the phylogenetic scale, as well as the embryologic scale, of mammals. Nucleation of erythrocytes occurs in the early mammalian fetus as well as in the phylogenetic scale below man. These features are similar to the changes that occur in pernicious anemia as the anemia is relieved by therapy. It was also found that fetal liver extracts were not potent in curing pernicious anemia. Because of these analogies with the condition found in pernicious anemia during relapse, it was decided to attempt to produce pernicious anemia in very young animals. Newborn pigs were used as the experimental animal because of their size and because this animal is a source of commercial liver extract.

Initially it was found that the basic experimental diets were deficient in the water-soluble vitamins, and yeast was consequently added. But this was found to contain blood-regenerating substances, and synthetic vitamin B products were therefore substituted when they became available. In a large group of pigs on this inadequate diet a few animals developed a macrocytic anemia; but all the animals developed marked ataxia. Pathologically the findings in the central nervous system resembled those of pernicious anemia except in lack of degeneration in the lateral funiculi.

A summary of the experiments of Dr Wintrobe revealed that animals on inadequate yeast intake were not protected from the development of ataxia by thiamin, riboflavin or nicotinic acid, singly or in any combination, yeast, even in huge doses, did not protect all the animals, although those which eventually became ataxic were carried on for long periods without ataxia, control experiments ruled out inanition as the cause of the nervous system changes, addition of whole liver completely protected the animals, wheat germ oil gave no protection. The effect of various liver fractions is now being investigated, and the indications are that the Cohn fraction is protective, whereas the Whipple fraction is not, recent observations indicate that protection is given by vitamin B₁₂, choline and pantothenic acid in combination, or possibly by one of these alone.

The relation of these experiments to pernicious anemia is still indirect and uncertain, Dr Wintrobe stated. However, it has been found that liver extracts made from ataxic pigs are ineffective in treating pernicious anemia, in contrast to those from pigs on adequate diets including liver or potent yeast. The puzzling question is, if the pigs' livers are lacking in the antipernicious anemia factor, why do these animals not develop macrocytic anemia?

Dr Wintrobe suggested that pernicious anemia may be a syndrome resulting from a deficiency of several factors, such as that found in pellagra. If this is so, the distribution of the factors in usual diets would explain why one person develops hematologic manifestations, another neurologic and another gastrointestinal. This is borne out clinically by the cases of severe anemia without symptoms in the central nervous system, and those with severe combined system disease and minimal macrocytic anemia.

During the discussion Dr Wintrobe answered questions posed by the audience. The amount of liver extract employed in his experiments was comparable to the human therapeutic dosage. Yeast is variable in its content of anti-anemic factors, depending on the mode of manufacture. The speaker cited the results of Strauss and Castle in obtaining a reticulocyte response by feeding yeast with gastric juice. Dr Wintrobe obtained similar results with large doses of yeast alone in those patients who were able to respond to oral therapy. The presence of achlorhydria was variable in controls and experimental animals. It appeared and disappeared from time to time and therefore was not considered significant. No consistent buccal mucosal changes were noted.

NOTICES

HARVARD MEDICAL SOCIETY

There will be a meeting of the Harvard Medical Society on Tuesday, February 11, in the amphitheater of the Peter Bent Brigham Hospital at 8 15 p.m. Dr Soma Weiss will preside.

PROGRAM

Presentation of cases
Pneumonia Dr Maxwell Finland

Beginning with the February 11 meeting, the Harvard Medical Society will meet on the second Tuesday of each month rather than bimonthly as in the past.

SOUTH END MEDICAL ASSOCIATION

There will be a meeting of the South End Medical Club at the headquarters of the Boston Tuberculosis Association,

554 Columbus Avenue, Boston, on Tuesday, February 18, at 12 m. Dr Frank R. Ober will speak on 'Chronic Arthritis'.

Physicians are cordially invited to attend.

BOSTON DOCTORS SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will rehearse under Alexander Thiede, formerly concert master of the Cleveland Symphony Orchestra, every Thursday at 8 30 p.m. Those interested in becoming members should com-

municate with Dr Julius Loman, Pelham Hall Hotel, Brookline (BEA 2430).

MASSACHUSETTS MEMORIAL HOSPITALS

There will be a research conference at the Robert Dawson Evans Memorial, 78 East Concord Street, Boston, on Wednesday, February 12, at 5 p.m. Dr Wilham E. Long will speak on 'Mapharsen in the Treatment of Forty Patients Following Arspenamine Dermatitis'.

Physicians and medical students are invited to attend.

SUFFOLK CENSORS MEETING

The censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, Boston, on Thursday, May 1, at 4 00 p.m.

Candidates should make personal application to the secretary and present their medical diplomas at least six weeks before examination (if graduates of foreign medical schools or schools not on the list recognized by the Council at least eight weeks before).

JOSEPH H PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM, FEBRUARY

Tuesday, February 11—Blood Transfusion. Past, present and future. Dr H G Brugsch.

Wednesday, February 12—Hospital case presentation. Dr S J Thannhauser.

Thursday, February 13—Artificial Pneumoperitoneum. Dr O B Lewis.

Friday, February 14—Certain Aspects of Leukemia. Dr Henry Jackson, Jr.

Saturday, February 15—Hospital case presentation. Dr S J Thannhauser.

Tuesday, February 18—The Psychosomatic Problem. Its significance for the physician. Dr Kurt Goldstein.

Wednesday, February 19—Hospital case presentation. Dr S J Thannhauser.

Thursday, February 20—The Perennial Tonsil Problem. Dr W A MacColl.

Friday, February 21—Some Characteristics of Experimental Deficiency Diseases. Dr O A Bessey.

Tuesday, February 25—X-ray demonstration. Dr Alice Ettinger.

Wednesday, February 26—Hospital case presentation. Dr. S. J. Thannhauser.
 Thursday, February 27—Advances in chemotherapy. Dr. C. A. Janeway.
 Friday, February 28—Gastrointestinal clinic. Dr. K. S. Andrews.

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held at the Beth Israel Hospital on Monday, February 24, at 8:15 p.m.

PROGRAM

- Demonstration of a Method Useful in Teaching Electrocardiograph. Dr. J. E. F. Riseman.
- The Incidence and Location of Occlusions in the Various Coronary Arteries. Dr. M. J. Schlesinger.
- Postoperative Thrombophlebitis: Factors impeding circulation and changes in venous pressure during abdominal operations. Drs. David Davis and Samuel Gilman.
- Cardiovascular Dynamics in Patients with Superior Caval Obstruction. Dr. M. D. Altschule.
- An Unusual Problem in Differential Diagnosis: With x-ray demonstration. Drs. Karl Presser and S. A. Robins.
- Further Studies in the Appraisal of Therapeutic Measures for Angina Pectoris. Dr. A. S. Freedberg.
- The Relation Between Electrocardiographic Changes and Coronary Artery Pathology. Drs. P. M. Zoll and Erwin Spiegl.

Interested physicians and medical students are cordially invited to attend.

NEW ENGLAND DERMATOLOGICAL SOCIETY

The next regular meeting of the New England Dermatological Society, which was scheduled for February 12 at the Massachusetts General Hospital, has been canceled because of the proximity of the Atlantic Dermatologic Conference to be held on March 22.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

There will be a meeting of the New England Society of Physical Medicine at the Hotel Kenmore, Boston, on Wednesday, February 19, at 8:00 p.m. A business meeting at 6:00 p.m. will be followed by an informal dinner in the Empire Room at 6:30 p.m.

PROGRAM

Medical Preparedness. Dr. Walter G. Phippen, president, Massachusetts Medical Society.

All members of the medical profession are cordially invited to attend.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The general oral and pathological examinations (Part II) for all candidates (Groups A and B) will be conducted at Cleveland, Ohio, by the entire board from Wednesday, May 28, to Monday, June 2, inclusive, prior to the opening of the annual meeting of the American Medical Association.

Application for admission to Group A, Part II, exam-

inations must be on file in the secretary's office not later than March 1.

Formal notice of the time and place of these examinations will be sent each candidate several weeks in advance of the examination dates.

Candidates for re-examination in Part II must make written application to the secretary's office before April 15, 1941.

In accordance with the previously announced plans of the board, the examinations to be given for the board's fiscal year 1941-42 (ending with the Part II examination in June, 1942) will be the last for candidates under Group A and B classifications. Applications must be in the secretary's office at least ninety days in advance of the announced examination dates, which dates are published in the various medical journals. Following the close of the final date for receipt of Group B applications (October, 1941) and Group A applications (March, 1942) all candidates will be considered in one classification by the board thus doing away with the junior and senior groups for examination, and all candidates will be required to take the Part I examination (written paper and submission of case histories) as well as the Part II examination (oral and pathological).

Military service will not affect the eligibility of any candidate so far as the board requirements regarding limitation of practice are concerned. Military service will under no circumstances be considered as an infringement of any regulations outlined in this board's booklet.

The board requests that all prospective candidates who plan to submit applications in the near future request and use the new application form which has been inaugurated by the board this year. The secretary will be glad to furnish these forms on request, together with information regarding board requirements. Address: Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh (6), Pennsylvania.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, FEBRUARY 9

SUNDAY, FEBRUARY 9

- 14 p.m. Medical Problems Presented by Selective Service. Dr. Frederick F. Russell. Free public lecture. Harvard Medical School, Building D.
- 14 p.m. Immunization Against Contagious Diseases. Dr. Charles F. Walcott. Cambridge Hospital, Margaret Jewett Hall.

MONDAY, FEBRUARY 10

- 12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

TUESDAY, FEBRUARY 11

- *9-10 a.m. Blood Transfusion: Past, present and future. Dr. H. G. Brugsch. Joseph H. Pratt Diagnostic Hospital.
- 12:15-1:15 p.m. Clinicorontogenological conference. Peter Bent Brigham Hospital amphitheater.
- 8 p.m. Boston City Hospital, Dowling Surgical Building. New England Society of Anesthesiology.
- *7:45 p.m. The Present Status of Physiotherapy in the Treatment of Chronic Arthritis. Dr. Arthur L. Watkins. Robert Breck Brigham Hospital.
- 8:15 p.m. Harvard Medical Society. Amphitheater, Peter Bent Brigham Hospital.

WEDNESDAY, FEBRUARY 12

- *9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.
- *12 m. Clinicopathological conference. Children's Hospital.
- *2-4 p.m. Obesity. Drs. J. C. Aub and F. C. Newton. Peter Bent Brigham Hospital.
- *5 p.m. Mapharsen in the Treatment of Forty Patients Following Arspenamine Dermatitis. Dr. William E. Long. Massachusetts Memorial Hospitals.

THURSDAY FEBRUARY 13

*8:30 a.m. Combined clinic of the medical surgical orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital at the Peter Bent Brigham Hospital

*9-10 a.m. Artificial Pneumoperitoneum Dr O B Lewis Joseph H Pratt Diagnostic Hospital

*8:15 p.m. Alcoholism Dr Merrill Moore United States Naval Hospital Chelsea

FRIDAY FEBRUARY 14

*9-10 a.m. Certain Aspects of Leukemia Dr Henry Jackson Jr Joseph H Pratt Diagnostic Hospital

SATURDAY FEBRUARY 15

*9-10 a.m. Hospital case presentation Dr S J Thannhauser Joseph H Pratt Diagnostic Hospital

*Open to the medical profession
†Open to the public

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information

in regard to all listed books will be gladly furnished on request.

Photodynamic Action and Diseases Caused by Light By Harold Francis Blum, Ph.D. The Washington Biophysical Institute 8°, cloth, 309 pp., with 25 tables and 50 illustrations New York Reinhold Publishing Corporation, 1941 \$6.00

The Role of the Liver in Surgery By Frederick Fitzhbert Boyce, M.D., visiting surgeon, Charity Hospital of Louisiana at New Orleans, French Hospital, Mercy Hospital, Hotel Dieu, Southern Baptist Hospital and Touro Infirmary 4°, cloth, 365 pp., with 44 illustrations Springfield, Illinois Charles C. Thomas, 1941 \$5.00

A History of Medicine By Arturo Castiglioni, M.D., research associate in the history of medicine, Yale University Translated from the Italian and edited by E. B. Krumbhaar, M.D., Ph.D., honorary president of the American Association of the History of Medicine 8°, cloth, 1013 pp., with 443 illustrations New York Alfred A. Knopf, 1941 \$8.50

What Are the Vitamins? By Walter H. Eddy, Ph.D., director of Good Housekeeping Bureau, and professor of physiological chemistry, Teachers College, Columbia University 8°, cloth, 247 pp. New York Reinhold Publishing Corporation, 1941 \$2.50

Modern Drug Encyclopedia and Therapeutic Guide By Jacob Guttman, M.D., Ph.D., director, Brooklyn Diagnostic Institute, and consulting physician, Manhattan General Hospital, New York City, and the Riverdale, Shore Road, Williamsburg Maternity and Borough Park General hospitals, Brooklyn Second edition 8°, cloth, 1644 pp. New York New Modern Drugs, 1941 \$7.00

Bacteriology in Neuropsychiatry A survey of investigations concerned with the specific role of infections and immune processes By Nicholas Kopeloff, Ph.D., research bacteriologist, New York State Psychiatric Institute and Hospital, New York City 8°, cloth, 316 pp., with 11 tables Springfield, Illinois Charles C. Thomas, 1941 \$4.50

Food, Teeth and Larceny By Charles A. Levinson, D.M.D. 8°, cloth, 232 pp. New York Greenberg, 1940 \$3.00

A Textbook of Clinical Neurology By J. M. Nielsen, M.D., associate clinical professor of medicine (neurology), University of Southern California, senior attending physician (neurology), Los Angeles County General Hospital, and attending neurologist, Hospital of the Good Samaritan, Los Angeles 4°, cloth, 672 pp., with 179 illustrations New York Paul B. Hoeber, Incorporated, 1941 \$6.50

The Extra Ocular Muscles A clinical study of normal and abnormal ocular motility By Luther C. Peter, M.D., Sc.D., LL.D., professor emeritus of diseases of the eye, Graduate School of Medicine, University of Pennsylvania, member of consulting staff, Graduate Hospital, University of Pennsylvania, and consulting ophthalmologist, Rush Hospital for Consumption and Allied Diseases, Friends' Hospital for Nervous and Mental Diseases and Roxborough Memorial Hospital Third edition, thoroughly revised 8°, cloth, 368 pp., with 147 illustrations and 5 colored plates Philadelphia Lea and Febiger, 1941 \$4.50

Diseases of the Digestive System Edited by Sidney A. Portus, M.D., associate clinical professor of medicine, Rush Medical College, University of Chicago, attending physician, Michael Reese Hospital, and consulting physician, Cook County Hospital, Chicago 8°, cloth, 952 pp., with

176 illustrations and 37 tables. Philadelphia: Lea and Febiger, 1941. \$10.00.

Medicine and Health in New Zealand: A retrospect and a prospect. By Douglas Robb, M.D., Ch.M., F.R.C.S. (Eng.). 8°, cloth, 146 pp. Auckland, New Zealand: Whitcombe and Tombs, Limited, 1940. 8/6.

Studies on the Human Thyroid in Iceland. By Julius Sigurjónsson. 8°, paper, 130 pp., with 21 tables and 10 figures. Reykjavik: Prentsmidjan Edda H. F., 1940. 6s. Obtainable from H. K. Lewis and Company, Limited, London.

Plague on Us. By Geddes Smith, M.D. 8°, 365 pp., with 24 illustrations. New York: The Commonwealth Fund, 1941. \$3.00.

Strange Malady: The story of allergy. By Warren T. Vaughan, M.D. 8°, cloth, 268 pp., with 23 illustrations. New York: Doubleday, Doran and Company, Incorporated, 1941. \$3.00.

Radiologic Physics. By Charles Weyl, B.S., M.S.; S. Reid Warren, Jr., B.S., Sc.D.; and Dallett B. O'Neill—Moore School X-Ray Laboratory, Moore School of Electric Engineering, University of Pennsylvania. With a foreword by Eugene P. Pendergrass, M.D., director of the Department of Radiology, University of Pennsylvania. 8°, cloth, 460 pp., with 166 illustrations and 33 tables. Springfield, Illinois: Charles C Thomas, 1941. \$5.50.

The Medical Reports of John Y. Bassett, M.D. The Alabama Student. With an introduction by Daniel C. Elkin, M.D., Joseph B. Whitehead Professor of Surgery, Emory University. 12°, cloth, 62 pp., illustrated. Springfield, Illinois: Charles C Thomas, 1940. \$1.50.

A Textbook of Clinical Pathology. Edited by Roy R. Kracke, M.D., professor of pathology and bacteriology, Emory University; and Francis P. Parker, M.D., assistant professor of pathology and bacteriology, Emory University. Second edition. 8°, cloth, 780 pp., with 223 illustrations, 26 tables and 34 colored plates. Baltimore: Williams and Wilkins Company, 1940. \$6.00.

BOOK REVIEWS

Sex in Marriage. By Ernest R. Groves, B.D., and Gladys Hoagland Groves. 12°, cloth, 250 pp. New York: Emerson Books, Inc. \$2.00.

With characteristic frankness and in a pleasing style the Groveses have made an addition to what is now becoming a small library by these authors on the subject of family adjustments. The reader who is acquainted with their previous writings will find nothing particularly new in attitude or style of presentation. Those who have read a number of the present-day frank studies in sex will find in this book little new information and nothing that tends to stimulate erotic interest. It does not deal with descriptions of deviations so much sought after by the curious minded. It is a book that could be put into the library of any home and should be available to the adolescent and young adult when parents desire to create a wholesome and factual attitude toward sex.

The reviewer does not wish to create the impression that this is a book far from that. There are ten chapters. The book deals with sex in its relation to happiness and marriage. It is a plea for an understanding of the rights and responsibilities of the individual in the family. It upholds the value of the family as a unit. It is a book for the young and the old. It is a book for the man and the woman. It is a book for the individual and the community. It is a book for the present and the future.

ing one's own background in making marriage adjustments, and this is followed by an interesting and practical statement regarding emotional problems arising from courtship.

The chapter on "Sex Equipment" is good, but its value would have been increased tenfold by the use of descriptive charts. To the visual minded nothing can take the place of pictures in the comprehension of physical structure and functioning.

In the chapter "The Beginnings of Marriage" there is a weakness that probably lies in the authors' withdrawal from any consideration of emotional deviations. It is too big a problem to discuss in a review, and if not fully considered, analysis might be unfair to the authors. The reviewer is constrained, however, to make the point that there is an error in the assumption that "cave-man tactics" are always disagreeable to the woman. There is a failure here to recognize that there are many women whose masochistic response to this somewhat sadistic approach is altogether satisfying. It seems a mistake to assume that such women are not normal. There is too great a tendency on the part of all authors to assume that those things with which they disagree and toward which they have a personal distaste are not normal, and that normality can be measured only by their own standards.

The subsequent chapters are interesting and instructive. On the whole it is a book that one need have no hesitancy in recommending to those who seek enlightenment on this subject.

Physical Diagnosis. By Ralph H. Major, M.D. Second edition, revised. 8°, cloth, 464 pp., with 437 illustrations. Philadelphia and London: W. B. Saunders Company, 1940. \$5.00.

The second edition of Dr. Major's textbook is even more attractive than the first. Its lively style, its wealth of historical allusions and its quotations from original and classic sources hold the reader's interest. The author is not afraid to append lists of bibliographic references to his chapters. A number of inaccuracies that marred the first edition have been corrected. The illustrations are abundant and good. The caption under Figure 373 on page 357, "Trophic changes in fingernails in pernicious anemia," should in the interest of accuracy be altered to "Spoon nails in anemia due to iron deficiency."

The March of Medicine. Edited by the Committee on Lectures to the Laity of the New York Academy of Medicine. 8°, cloth, 168 pp. New York: Columbia University Press, 1940. \$2.00.

Recently the laity has shown much interest in the history of medicine, and the New York Academy of Medicine has been foremost in fostering this trend. The book is the fourth in the series, "Lectures to the Laity." The contributors, eminent in the field they have chosen to discuss, are Drs. Walter C. Alvarez, Sanford V. Larkey, Cecil K. Drinker, Charles G. Heyd, R. G. Hoskins and Karl A. Menninger. The preface is written by Dr. Malcolm Goodridge, president of the New York Academy of Medicine, who emphasizes the thesis, "Without the intelligent co-operation of the lay people, the full application of the advance in medical science will never be possible." The topics that make up these lectures are as follows: "From Folkways to Modern Medicine," "Health in Elizabethan England," "Not So Long Ago," "The Romance of Modern Surgery," "The Story of Insanity," and "The Cinderella of Medicine." This book may be read with equal interest and instruction by the layman, the medical student and the physician.

STUDIES ON HEMOGLOBIN REGENERATION IN PATIENTS WITH VITAMIN C DEFICIENCY¹

EUGENE L. LOZNER, M.D.†

BOSTON

IN 1930, Mettler, Minot and Townsend¹ observed the occurrence of anemia in nine patients with clinical signs of scurvy, which was relieved by fruit, green vegetables and fresh liver, but in two cases was unrelieved by either iron or liver extract of the type effective in pernicious anemia. The remission of the anemia was attributed to the richness of these foods in vitamin C, and the conclusion was drawn that a specific anemia due to vitamin C deficiency probably existed. The subsequent isolation, crystallization and synthesis of vitamin C, the development of methods for its estimation and the realization that foods rich in vitamin C may be sources of iron, vitamin A and vitamin B complex, made it desirable that this concept be investigated further.

The available data in the literature are difficult to evaluate because of the lack of a control period in most cases, and because many observers have used orange juice rather than pure ascorbic acid. All the reported cases treated with orange juice showed beneficial effects on the anemia. In this category belong the clinical and experimental data of Mettler, Minot and Townsend,¹ Mettler and Chew,² Parsons and Hawksley³ and Jennings and Glazebrook.⁴ Besides vitamin C, orange juice is known to contain iron and vitamin A and vitamin B complex.⁵ The suggestion has already been made that it may be necessary to explain the anemia of scurvy on the basis of deficiency of factors other than ascorbic acid.⁶

The data with respect to the effects of ascorbic acid are far less conclusive. Kenney and Rapoport⁷ treated 5 anemic infants with scurvy. In none was there any control period. The anemia of 2 of the infants improved during vitamin C

therapy alone. In the remaining 3, however, no improvement took place until iron was administered. Vaughan⁸ has reported a scorbutic patient in whom it was apparently necessary to administer ascorbic acid to control the anemia. The peak of reticulocytosis occurred, however, on the third day following ascorbic acid administration, which makes one speculate as to whether this was too soon for a true causative relation. Croft and Snorf⁹ could find no correlation between anemia and low vitamin C levels, nor did they get any reticulocytosis in 6 cases with "secondary anemia" and very low vitamin C levels by using synthetic vitamin C. Aron¹⁰ reported the failure of response of the anemia of experimental scurvy to ascorbic acid administration but noted its successful treatment with germinated oats. Three cases of scurvy with anemia observed by Ungley¹⁰ showed reticulocytosis and hemoglobin regeneration on a vitamin C free diet; a specific effect due to ascorbic acid administration could not be demonstrated. Dunlop and Scarborough¹¹ reported observations on 2 adults with scurvy in whom ascorbic acid apparently facilitated hemoglobin regeneration but produced no reticulocytosis.

The sporadic occurrence of a reticulocytosis without hemoglobin regeneration following ascorbic acid administration has been reported by Faulkner¹² and by Hall, Darling and Taylor.¹³ Two of the scorbutic infants of Kenney and Rapoport⁷ presented this phenomenon.

Indirect evidence bearing on this problem is presented by the work of Moore et al.¹⁴ on the relation between serum iron and ascorbic acid levels. They have shown that administration of iron results in a decrease in plasma ascorbic acid concentration. The converse, however, is not true, and ascorbic acid administration has no apparent effect on serum iron levels.

It is therefore evident that the existing data concerning the necessity of ascorbic acid for the

¹From the Thorek Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

The expenses of this paper were defrayed in part by a grant given in honor of Francis Weld Peabody by the Ella Sachs Plotz Foundation.

†Resident physician, Thorek Memorial Laboratory, Boston City Hospital, assistant in medicine, Harvard Medical School.

regeneration of hemoglobin are largely inconclusive. It is the purpose of this communication to report observations concerning hemoglobin regeneration in 5 patients with presumptive vitamin C deficiency and anemia, with particular reference to the necessity for ascorbic acid administration.

METHODS

Five patients with presumptive vitamin C deficiency, as shown by complete chemical absence of reduced ascorbic acid from the blood plasma, were treated with bedrest and a diet limited to the following foods: whites of eggs, white bread, white soda crackers, butter, spaghetti, rice, bacon, corn syrup, tea, coffee and milk boiled for five minutes. None of these foods contain more than a trace of vitamin C or of vitamin B complex.

Three of the patients presented the clinical picture of scurvy, one pellagra, and the fifth idiopathic hypochromic anemia. All showed complete absence of reduced ascorbic acid from the blood plasma. Three patients had a moderate anemia, and in the others a mild anemia was rendered more severe by removal by venesection of 1600 cc. of blood.

Counts of the red and white cells, hematocrit determinations and hemoglobin estimations by a modification of the Klett-Summerson photoelectric-cell method¹⁵ were made on venous blood every other day. Reticulocyte percentages were determined on capillary blood every day. Determinations of the plasma ascorbic acid by the methods of Mindlin and Butler¹⁶ revised for the Klett-Summerson photoelectric colorimeter were made twice a week.

Abstracts of the case histories are as follows:

CASE 1. A 49-year-old unemployed white man, who had lived alone and cooked his own meals for the last 3 years, subsisting on a diet markedly deficient in fruits and green vegetables, three weeks before admission developed ecchymoses over both legs and swollen, spongy, purple, protruding, painful gums that bled easily. Six years before entry, a diagnosis of tertiary syphilis had been made, and he had been given intensive specific therapy. There was no history of alcoholism. The tourniquet test was positive. Urine and stool examinations were negative. Gastric analysis showed normal acidity. A diagnosis of scurvy was made.

CASE 2. A 55-year-old widower, who following the death of his wife lived alone for nine years, cooking his own meals and subsisting on a diet markedly deficient in fruits and green vegetables, seven weeks before admission developed large ecchymoses over both legs; three weeks later his gums became swollen and spongy and bled on the slightest trauma. There was no history of alcoholism. The tourniquet test was positive. Urine and stool examinations were negative. A blood Hinton test was positive. A diagnosis of scurvy was made.

CASE 3. A 67-year-old white man with a 20-year history of postprandial distress and occasional tarry stools un-

relieved permanently by appendectomy 20 years and gastroenterostomy 14 years previously, had subsisted for 5 years prior to entry on tea, white bread, milk, cream and coffee. Three months before admission he began to develop ecchymoses over both legs, and the postprandial distress recurred. The tourniquet test was positive. Urine examination was negative. A blood Hinton test was negative. Stool examination was markedly positive for occult blood. Gastric analysis showed normal acidity. X-ray examination of the stomach showed a small gastric ulcer and pyloric obstruction. Diagnoses of scurvy, gastric ulcer and pyloric obstruction were made.

CASE 4. A 49-year-old single laborer for 2 years had consumed between a pint and a quart of whiskey daily and had eaten irregularly and inadequately. Two weeks before admission, following exposure to the sun, the backs of both his hands became red, swollen, painful and blistered. The tourniquet test was positive. The urine and stool examinations were negative. A blood Hinton test was negative. Diagnoses of alcoholic pellagra and subclinical scurvy were made.

CASE 5. A 50-year-old housewife, subsisting on a diet slightly deficient in fruits and vegetables, complained of dysphagia of 5 years' duration and dysuria and dyspnea of 1 year's duration. She had had nine pregnancies. A marked hypochromic anemia was present. Examinations of the urine showed mild pyuria and bacilluria (colon bacillus). Stool examination was negative. A blood Hinton test was negative. Gastric analysis showed achylia. Diagnoses of chronic cystitis and idiopathic hypochromic anemia were made.

RESULTS

A summary of the results is presented in Table 1. It will be observed that 4 of the 5 patients showed satisfactory hemoglobin regeneration without vitamin C administration, even though they were kept on a diet containing only traces of vitamin C and vitamin B complex. In 3 of these 4 patients, ascorbic acid, administered after the initial period of hemoglobin regeneration, neither caused reticulocytosis nor increased the speed of hemoglobin increase. The remaining patient had clinical scurvy associated with melena and anemia. During the control period, neither the melena nor the anemia disappeared. Coincident with the administration of vitamin C, the melena ceased, and reticulocytosis and hemoglobin regeneration ensued.

It is also of interest to note that in 2 patients (Cases 2 and 5) complete regeneration of hemoglobin did not occur until after they were placed on yeast and a general diet.

DISCUSSION

The observations reported here confirm those of Ungley¹⁰ and support the suggestion of Croft and Snorf that it is possible that synthetic vitamin C is not the antianemic factor in scorbutic anemia, and that the universal success with orange juice may be attributed to a factor other than reduced ascorbic acid. Since orange juice contains vitamin B

complex, it is conceivable that one of the anti-anemic factors shown by Wills and Evans,¹⁷ Miller and Rhoads,¹⁸ and others,^{19, 20} to be concerned in various experimental anemias may also be concerned in the anemia of scurvy. This speculation is particularly inviting because of the original report of Mettier, Minot and Townsend¹ that liver extract was not effective, whereas raw liver pulp was, which is exactly what Wills has found in tropical macrocytic anemia.

Crandon and Lund²¹ have recently reported studies on a normal active adult on a vitamin C free diet receiving supplements of iron and every known vitamin except vitamin C for four months. During this period, despite blood loss of 2300 cc. by venesection for experimental reasons, the hemoglobin and red-cell count fell only slightly below their initial values and were quickly restored to normal levels by the ingestion of ferrous sulfate. During two additional months on the vitamin C free diet,²² manifest scurvy developed, but in spite of blood loss by venesection of 2400 cc. more, neither the hemoglobin nor the red-cell count fell. Thus, in a normal man on a vitamin C free diet for six months, during which manifest scurvy developed, and in spite of blood loss by venesection totaling 4700 cc., no anemia developed. This is confirmatory of the conclusions drawn here.

It is necessary to comment on the significance of the chemical absence of ascorbic acid from the plasma, which has been taken here as presumptive evidence of considerable deficiency of this factor. This is in agreement with most authorities.²³ It must be borne in mind, however, that the absence of ascorbic acid from the plasma implies complete absence from neither the blood nor the tissues. This is clearly demonstrated by the recent work of Butler and Cushman.²⁴ It is therefore conceivable that the anemia that has been described as due to vitamin C deficiency may not occur until the body is completely depleted of this vitamin.

The role of blood loss in the development of the anemia accompanying scurvy is unsettled. Two facts seem to point to its significance. The first is that scurvy is essentially a hemorrhagic disorder and, in common with analogous conditions, might be expected to be accompanied by an iron-deficiency anemia. The other is the reticulocytosis that many patients with scurvy present on admission to the hospital. This phenomenon has been observed by Ungley¹⁰ and Dunlop and Scarborough¹¹ and was presented by Cases 1 and 3 reported here. Added evidence that blood loss may be significant in the anemia accompanying scurvy is offered by Case 3. This patient had melena,

which did not cease until ascorbic acid was administered; coincident with the cessation of blood loss, hemoglobin regeneration occurred.

SUMMARY AND CONCLUSIONS

Observations on regeneration of hemoglobin were made in 5 patients with moderate anemia and with presumptive vitamin C deficiency, as indicated by total absence of reduced ascorbic acid from the plasma. In 4 patients regeneration of hemoglobin took place spontaneously or in response to iron therapy alone. It is concluded that hemoglobin regeneration may occur in the absence of reduced ascorbic acid from the blood by chemical test.

SULFANILAMIDE IN THE TREATMENT OF ACUTE PELVIC INFLAMMATORY DISEASE*

JOHN T. WILLIAMS, MD †

BOSTON

THE striking results of sulfanilamide therapy in streptococcal infections and acute gonorrhea reported by numerous observers have led the members of the Gynecological and Obstetrical Service at the Boston City Hospital to extend the application of this drug to the treatment of acute pelvic inflammations. It would be superfluous to review the literature on sulfanilamide therapy. The list of papers on the use of sulfanilamide in streptococcal and gonococcal infections in women comprises over one hundred and fifty references. In marked contrast to this extensive literature, there is a paucity of evidence of the use of the drug in the common types of acute pelvic inflammation.

Gillette,¹ writing on the use of sulfanilamide in infections of the upper genital tract in women, reported a series of 50 cases. Of 16 patients with adnexal masses, 5 were improved, 6 showed no change and in 5 the masses increased in size in spite of the treatment. In 25 cases of recurrent salpingo-oophoritis, 5 showed only "adnexal thickening," and of these 4 became afebrile in five days. In 8 cases with large inflammatory masses, there was no improvement. In 12 patients with small adnexal masses, there was some diminution in size in 5 and no change in 7. Gillette considered sulfanilamide therapy to be more effective during the initial attack than later.

Goff,² with a rather small experience, concluded that in patients seen during the first three days of gonorrheal pelvic infections the process could be aborted by sulfanilamide, but that in those seen later, when mass formation had occurred, improvement was much slower.

Manor,³ in a study of gonorrheal infections of the lower genital tract, found that 36 per cent of the patients also had intrapelvic inflammatory disease. These showed some improvement after the use of sulfanilamide.

Barringer and her associates⁴ noted that adnexal masses lost their tenderness and in some cases diminished in size under sulfanilamide therapy. Increased mobility of the uterus followed. According to their observations, 18 cases were improved, but 12 others showed no improvement.

Sulfanilamide therapy in acute pelvic inflammations has been carried on for more than a year

on our gynecologic wards. We have thus been able to secure accurate data on 72 cases. To find out more definitely what benefit was derived from the use of sulfanilamide, an analysis has been made of 100 patients—as nearly as possible parallel to those who received sulfanilamide—who were treated during the presulfanilamide era by the routine of bedrest, fluids, catharsis, ice or heat to the abdomen and hot vaginal douches. It should be stated here that the patients who were given sulfanilamide received in all other ways the same treatment as the control series. We believed that a comparison of the results in these two series would give a clear idea of the value of sulfanilamide therapy in pelvic inflammatory disease. There were no fatalities in either series.

Although varying degrees of clinical severity appeared in different patients in each series, all presented the following characteristics: elevation of temperature to 101°F or over, acute pain and tenderness, spasm or palpable masses—usually both—at the same or different periods of the process, leukocytosis and vaginal discharge. The majority of these attacks began either during or, more commonly, just after a menstrual period. One point that stands out very clearly in our observations is that recurrent attacks were on the average of shorter duration than the initial attack.

In the series not receiving sulfanilamide, the temperature fell to normal within one week after admission in 72 per cent. Since the other symptoms, such as pain, tenderness and leukocytosis improved almost parallel with the fall in temperature, it seems sufficiently accurate to accept the latter as the measure of improvement. This criterion, therefore, will be used throughout this paper.

The average duration of the febrile reaction in the control series was 67 days. The longest duration of temperature elevation in any case was 35 days. In 63 patients suffering from their first attack the average was 79 days; in 37 patients with recurrent attacks it was 48 days.

Having established a definite standard for comparison of results, we turn to the series treated with sulfanilamide. The routine doses of sulfanilamide administered to patients thus treated were as follows: 120 gr. a day for the first two days, then 90 gr. a day until a definite fall in temperature was noted. The dosage was then cut

*From the Gynecological and Obstetrical Service, Boston City Hospital.

and assistant professor of gynecology, Harvard Medical School.

to 60 and later to 40 gr. daily, being omitted after forty-eight hours of normal temperature. Sodium bicarbonate was given with the sulfanilamide in proportions varying from 10 gr. of sodium bicarbonate to 30 gr. of sulfanilamide up to equal amounts of each.

Untoward effects were slight. All cases showed more or less cyanosis, but this was not regarded as a contraindication to continuing the drug. Vomiting occurred in some cases, but was not severe enough to interfere seriously with the treatment. The red-cell and white-cell counts were carefully followed, and the former were more seriously affected than the latter, but not uniformly.

It seems evident that the blood of certain patients is definitely susceptible to the action of sulfanilamide. Marked falls in the red-cell count were limited to a few patients who showed decreases of from 1,000,000 to 1,400,000. The majority showed very slight drops in red-cell count. A few actually showed an increase in red cells while they were under treatment with sulfanilamide, due no doubt to improvement in the general condition from rest and proper diet. In four patients showing marked falls in the red-cell count, transfusion and cessation of medication were deemed advisable.

The white-cell count always dropped in the sulfanilamide-treated patients, but in some it rose at the beginning of the treatment before the sulfanilamide had begun to act on either the corpuscles or the inflammatory process. In these cases, however, the white-cell count eventually dropped to a level lower than that at the beginning of treatment.

It was always difficult to tell how much of the decrease in white-cell count was due to the sulfanilamide and how much to the subsidence of the inflammatory process. In the series not treated with sulfanilamide the average drop was 5200, whereas in those treated with sulfanilamide it was 5500—not a significant difference. In the sulfanilamide series the leukocyte count in 1 case fell to 2400 from an original level of 12,200; the blood cells were carefully checked by the staff of the Thorndike Memorial Laboratory, and no evidence of agranulocytosis or of abnormal relations between the different types of leukocytes was obtained. This patient later went through operation without incident.

Seventy-two per cent of the sulfanilamide-treated patients showed a normal temperature within one week, exactly the same percentage as that of the untreated cases. The average time taken to produce a normal temperature was 5.8 days, a little less than one day shorter than that in the un-

treated cases; this is hardly a striking difference. In primary attacks (44 patients) the temperature elevation averaged 6.0 days, whereas in recurrent attacks (28 patients) the average was 5.7 days. The longest run of temperature was thirty-six days. In this patient the red-cell count fell from 3,600,000 to 2,400,000, and the white-cell count from 26,400 to 12,500 after continuous sulfanilamide therapy for eighteen days. Sulfanilamide administration was stopped, and after three transfusions the red-cell count was raised to 3,900,000; the patient ultimately recovered after developing a pelvic abscess that broke through into the rectum just as she was being prepared for colpotomy. In 1 case a pelvic abscess that formed while the patient was under sulfanilamide treatment was drained by colpotomy on the seventh day after admission; the temperature fell to normal two days later. These 2 cases must be regarded as absolute failures of sulfanilamide therapy.

Another question was whether or not sulfanilamide reduced in any way the number of patients ultimately requiring operation. Of course such statistics are somewhat influenced by the judgment of different operators. Thirteen per cent of the untreated series and 11 per cent of those who had received sulfanilamide were deemed to require salpingectomy. Abscess formation requiring vaginal drainage has already been referred to. In the sulfanilamide-treated series colpotomy was done on 3 of 72 patients, and in the untreated series on 4 of 100, the percentages being identical.

SUMMARY AND CONCLUSIONS

Seventy-two cases of acute pelvic inflammatory disease were treated with sulfanilamide. For purposes of comparison a careful analysis was made of 100 cases of acute pelvic inflammation treated in exactly the same way except that no sulfanilamide was given.

The dramatic results often obtained by sulfanilamide in streptococcal infections and by sulfanilamide and sulfapyridine in pneumonias were disappointingly absent.

The figures show that very little advantage was obtained by the administration of sulfanilamide. It is fair to state, however, that nearly all these patients had been ill at home for a considerable period before entering the hospital. It has been claimed, and may still be true, that sulfanilamide given in gonorrheal infections may prevent the development of tubal involvement; the drug is of little value, however, once the inflammatory process in the adnexa has become well established. Better results might be obtained if it were possible

to get these patients under treatment during the first twenty-four hours of the attack.

With careful blood checking no serious ill effects were experienced from the treatment. Marked damage to the red corpuscles appears to occur only in certain susceptible persons. The drop in the white-cell count is due more to subsidence of the inflammatory reaction than to the destructive effect of the drug on the white corpuscles.

The administration of sulfanilamide in acute pel-

vic inflammatory disease has now given better results than the former methods of treatment.

SPINAL ANESTHESIA IN OBSTETRICS, USING PONTOCAINE-CL

JOHN C. SHULL, M.D.,† AND EDWARD P. MANNING, M.D.

BOSTON

SPINAL anesthesia, which has found wide applicability for surgical procedures on the abdomen and lower extremities, has not been fully appreciated in obstetrics. Perhaps the reason for this is the effort of a few obstetricians who persist in the belief that spinal anesthesia is dangerous.^{1,2} Reports of successful use of spinal anesthesia coming from different parts of the country do not bear this out, and our experience at the Boston City Hospital leads us to believe that spinal anesthesia is safe if a few simple rules are followed, and that it is very useful for the delivery of selected cases.

The first record of the use of spinal anesthesia in obstetrics is that of Babcock,³ who reported a series of 53 cases, all operative. He made the observation that the uterine contractions continue after spinal anesthesia but, being without the normal aid of the voluntary expulsive forces, are inefficient even when supplemented by the associated relaxation of the pelvic outlet.

Cooke⁴ in 1923, reported a series of 25 cases, of which 6 delivered spontaneously. In 1927 Cosgrove⁵⁻¹⁰ wrote the first of several papers on the subject. On December 31, 1939, his series had grown to include 4880 cases (personal communication), and his papers contain a large amount of data on the subject. He reports 2 deaths, one a case delivered from below, the other in a ruptured ectopic pregnancy.

Stollenwerck¹¹ reported 140 cases. Pitkin, McCormack¹² reported a series of 89 cases delivered from below and 65 cesarean sections without accident. Fraser¹³ reported 64 cases

in the course of eight 150 cases and have considered spinal anesthesia but impressive total

We have devised a method of spinal anesthesia instead of 50 mg of spinal fluid, we use Pontocaine and Sise¹⁴ and add gravity. This is a fourth lumbar needle, with the patient in the position of the solution

The effect of the solution is dependent on scopolamine and the perineum is relaxed, and is a definite advance. The skin and fascia is still present, the incidence of episiotomies is reduced in our cases—in the multiparas there were episiotomies in 5. The degree lacerations in 5. The perineal manipulation is more difficult. We attempted with Pitkin¹⁶ the use of the performance

Gynecological Service, Boston City Hospital

ment. As will be discussed later, we agree with Cosgrove⁷ that spinal anesthesia is satisfactory only as an anesthetic for delivery and is not useful as an analgesic during the first or second stage of labor. We try to time the administration in multiparas at full dilatation, with the presenting part in the mid-pelvis or lower mid-pelvis, and in primiparas with the cervix fully dilated and the head low, or otherwise at the time of decision to intervene.

The most satisfactory level of anesthesia extends to the tenth thoracic segment, or just below the umbilicus, for uterine pain from contractions is completely abolished when this level is reached. Anesthesia to the second lumbar segment is sufficient for a low-forceps operation with episiotomy, although the patient is conscious of uterine pain of diminished intensity. The delivery may be postponed for about fifty minutes after the spinal injection, with no effect on the fetus. Usually in sixty to seventy-five minutes, contractions again become painful. However, the anesthesia to the perineum permits repair of lacerations without discomfort for about two hours.

In cesarean sections we use 8 to 12 mg. of Pontocaine (0.8 to 1.2 cc. of a 1 per cent solution and 1.5 cc. of glucose). Usually a sufficiently high level of anesthesia is obtained with the patient in the horizontal position. If the anesthesia has not risen sufficiently high in five minutes, the patient may be placed in a moderate Trendelenburg position for a few minutes. Ordinarily the patient is not placed in Trendelenburg for ten minutes after the injection, and usually not until the abdomen has been opened.

RESULTS

Deliveries from Below

In a period of three months, during which 750 cases were delivered at the Boston City Hospital, 150 patients were delivered from below under spinal anesthesia. This method was usually used in patients in whom an operative delivery was anticipated, and was routinely used for patients with a history of cough, for those with eclampsia, toxemia or heart disease and for those who had recently eaten. There were no maternal deaths and no stillbirths.

Supplementary anesthesia was required in 5 cases. In 4 of these the spinal anesthetic had been given too soon, so that the anesthesia had worn off before delivery could be safely effected. Three were among the first 8 patients on whom spinal anesthesia was tried. The fifth patient had no skin anesthesia, although uterine pain was abolished. In 2 additional cases, the anesthesia did not take effect, but a second injection produced a satisfac-

tory result. In 2 patients not included in the series, we were unable to get into the subarachnoid space. We found, therefore, that the anesthesia was effective in 145 of 152 cases, or 95 per cent. The relatively high incidence of successful anesthesia, in addition to the simplicity of the method, is the chief argument for the choice of spinal over sacral anesthesia.

In two cases not previously mentioned, the anesthesia was repeated because of early administration of the first injection. The second anesthesia was found to last about thirty minutes longer than the first, with no apparent harm to the patient.

The types of delivery are listed in Table 1. Six of the mid-forceps deliveries were done because the anesthetic had been given too soon; if the anesthesia had been postponed, low-forceps or normal

TABLE 1. *Types of Delivery.*

DELIVERY	PRIMIPARAS	MULTIPARAS	TOTAL
Normal	12	15	27
Low-forceps	91	12	103
Mid-forceps	12	0	12
Breech extraction	0	1	1
Footling extraction	1	1	2
Version	0	0	0
Scanloni	5	0	5
Totals	121	29	150

deliveries would probably have resulted. This error was made early in the series, and we believe that it is a matter of judgment in timing the administration. The conversion of a frank breech to a double footling was found to be difficult under spinal anesthesia, because of lack of uterine relaxation, and it was consequently attempted in only 1 case. For the same reason, version was not attempted under spinal anesthesia.

The youngest patient was sixteen years of age, the oldest forty-one. One hundred and seventeen of the patients were twenty-five years old or under. Two had eclampsia, and were delivered by low forceps of living babies; both were well when discharged. Included in the series were 4 cases of pre-eclampsia, 1 of severe, though compensated, rheumatic heart disease, 1 of mild rheumatic heart disease, 1 of severe bronchitis, 1 of asthma and 1 of pyelitis. Several patients were suspected of having pulmonary tuberculosis, but in no case was the diagnosis verified by x-ray.

In 129 cases the level of anesthesia was between the eleventh and fifth thoracic segments; in 10 cases it was above this, and in 9 cases below. In 1 case there was no dermal anesthesia, and in 1 the anesthesia was at the tenth thoracic segment on the right and the first lumbar on the left. One patient had anesthesia to the chin for a short time a half hour after the injection, but felt perfectly comfortable and had no drop in blood pressure.

There was a fall in blood pressure of 20 mm. or more of mercury following spinal anesthesia in 29 of the 150 cases. We believe that many of these were due to the relief from the bearing-down pains rather than to a change in the vascular bed. Fall to a critical level was noted in only 1 case, already mentioned, in which a large dose of Pontocaine had been used. Three minims of a 1:1000 solution of adrenalin hydrochloride intravenously was promptly effective in restoring the blood pressure and the patient's feeling of well-being.

A poorly acting post-partum fundus was noted in 8 cases; usually the uterus contracted well. The placenta was retained in 3 cases. Manual extraction of the placenta was found to be difficult in the 2 cases in which it was done.

Of the late complications encountered, headache was the most frequent. There were 5 severe headaches and 21 slight headaches, none lasting over six days. This is a percentage of 17 and agrees almost exactly with that of Cosgrove.¹⁰ This symptom is not nearly so frequently encountered in general surgical operations, and only 1 of 23 patients with cesarean section had a transitory headache. It seems, therefore, as Cosgrove⁷ suggested, that the changes of spinal-fluid pressure accompanying labor may be a causative factor. Treatment consisted in keeping the patient flat, applying an ice bag to the head and administering codeine and aspirin.

For twenty-four hours two patients had difficulty voiding. There were no pulmonary complications. One prolonged anesthesia of the leg and temporary paresis of the leg muscles following a Scanzoni manipulation was thought to be traumatic obstetric paralysis rather than a result of spinal anesthesia.

Cesarean Sections

During a period of six months 26 of a total of 38 cesarean sections were attempted under spinal anesthesia. In 2 cases the lumbar puncture was unsuccessful, and in 1 case only a saddle type of anesthesia was obtained so that a nitrous oxide-oxygen-ether anesthesia had to be used. The anesthesia was therefore satisfactory in 88 per cent of this small series. In 1 case the patient developed an extreme pruritus after medication, which caused so much restlessness that it was necessary to supplement the anesthesia with nitrous oxide after the delivery of the placenta.

In 22 cases a transverse cervical section was done, and in 1 a Porro.

There was an appreciable blood-pressure drop in only 2 patients, both of whom were operated on for bleeding from placenta previa. The blood pressures fell momentarily to 80 systolic, 58 diastolic, and 64 systolic, 40 diastolic, respectively;

neither case required extreme measures at the moment, but their course suggests that this may not be the best anesthesia for cases with bleeding.

Two cases were in labor. No difficulty was experienced in the extraction of the infant, although uterine contractions could be perceived.

Convalescence was uniformly satisfactory. There were no respiratory complications. There were no deaths and no stillbirths.

The advantages of spinal anesthesia for cesarean section seem to be complete relaxation of the lower abdominal musculature, the absence of any depressing effect on the fetus, and the exceptionally satisfactory convalescence.

DISCUSSION

Advantages and Disadvantages

We believe that spinal anesthesia should be used in patients with toxemia, eclampsia or nephritis; acute or chronic pulmonary conditions; upper respiratory infections; diabetes; and a full stomach. The anesthesia is also useful as a way of delaying labor without injury to the infant. For example, spinal anesthesia was to be used in the delivery of a private case, a multipara, because of a cough of six weeks' duration. Progress in the late first stage was unexpectedly rapid; although the obstetrician could not reach the patient within a reasonable time, spinal anesthesia permitted his delivery of the baby forty-five minutes later with no complications to mother or baby. Another feature of the anesthesia is that the patient may have the thrill of hearing her baby's first cry while having a painless delivery.

The absence of any narcotizing effect on the baby has made it possible to use morphine as a sedative in combination with Seconal and Sodium Amytal, with no marked depressant effect on the baby. Using 3 gr. of Seconal and 6 to 9 gr. of Sodium Amytal, with 1/6 gr. of morphine, we have noted a quiet restful analgesia that is in marked contrast with the analgesia dependent on scopolamine. Cosgrove⁷ first suggested that morphine might be safely used during delivery in combination with spinal anesthesia.

Relaxation of the vagina and the perineum is sometimes quite marked, and is a definite advantage. Tightness of the skin and fascia is still present, however, and the incidence of episiotomies was not greatly reduced in our cases—in the delivery of 121 primiparas there were episiotomies in 73 and second-degree lacerations in 5.

Any intrauterine manipulation is more difficult under spinal anesthesia. Although we attempted no versions, we disagree strongly with Pitkin,¹⁶ who advocates the use of large doses of a spinal anesthetic to relax the uterus for the performance

of version. Large doses may be dangerous, and the tone of the uterus is sufficiently great to make the procedure difficult, if not hazardous.

A further disadvantage is the increased incidence of forceps deliveries. To ensure a normal or low-forceps delivery, we advocate waiting for the head to come well into sight, if possible, in primiparas before administration of the anesthetic.

Physiologic Aspects

Three interesting observations concerning the physiology of labor have been brought to light by these studies, namely, the nerve pain paths associated with labor, the effect of spinal anesthesia on the cervix and the effect of spinal anesthesia on the rate, force and duration of uterine contractions.

Cleland¹⁶ has demonstrated experimentally that pain accompanying childbirth is a combination of a deep uterine pain, which can be blocked by anesthetizing the eleventh and twelfth thoracic segments on both sides, and a pain from the genital tract, which can be blocked by anesthetizing certain sacral roots. We have been able to confirm this in part by noting the effect on uterine pain of spinal anesthesia to different skin levels. There is complete relief from uterine pain when the anesthesia is an inch below the umbilicus or above this level. However, if a lower level of anesthesia is obtained, there is some pain with each contraction, but this pain is of diminished intensity. In the case in which the anesthesia level extended to the tenth thoracic segment on the right side and to the first lumbar on the left, the patient complained of left-sided uterine pain. If the sacral area alone is blocked, the patient notes a diminution of intensity of labor pain; it therefore seems that some of the pain fibers must enter by the sacral and lumbar roots as well as by the eleventh and twelfth thoracic roots.

We were particularly interested in the possibilities of the relaxing effect of spinal anesthesia on the cervix. In the French literature much is written concerning the rapid termination of pregnancy at term by using spinal anesthesia, a method originated by Delmas.¹⁷ To study the effect of spinal anesthesia on the cervix, two multiparous toxemic patients, who were to have their membranes ruptured for the induction of labor, were selected. Spinal anesthesia was administered, and a gentle digital invasion of the cervix was made. This demonstrated in both cases that there is no ready relaxation of the cervix secondary to the spinal anesthesia. Similarly in a patient whose cervix had been well effaced by labor, but was dilated to admit only two and a half fingers, vaginal examination with spinal anesthesia showed the cervix to be no more dilatable than without anesthesia.

It is suggested, therefore, that spinal anesthesia is not an adjunct to *accouchement forcé*.

The third interesting aspect of spinal anesthesia is that uterine contractions continue. This is partly due to the fact that sympathetic fibers from higher in the spinal cord are not blocked, because they descend in the lateral sympathetic trunks.

That the uterus does contract painlessly under spinal anesthesia can be demonstrated by palpating the abdomen. Likewise, at cesarean section under spinal anesthesia on a patient in labor, we have actually observed uterine contractions, as has Cosgrove.⁹ Pressure measurements can be made with a hydrostatic bag inserted into the uterus while the membranes are still intact, and then connecting the bag by a water-filled tube to a mercury manometer. Cosgrove⁹ reports such an experiment and states that there was no essential change in the power of contractions. However, Bourne and Burn¹⁸ performed a similar experiment using Stovaine as the anesthetic, and showed that contractions continued irregularly, but that the uterus did not relax to the same degree between contractions. They concluded that this contraction of the lower segment would slow labor if spinal anesthesia were given early, but would hasten labor if it were given at full dilatation. We have repeated this experiment, and our results did not completely corroborate either of the above observations. Following anesthesia the contractions that had been at regular intervals and of equal intensity and duration became irregular in time, in strength of contraction and in duration. There was no cessation of contractions during the first ten minutes, as is sometimes reported. The base line in our experience remained the same: about 40 mm. of mercury. This indicates a less effective type of labor, which in addition to the loss of voluntary muscle contraction in spinal anesthesia has the effect of checking the progress of labor.

SUMMARY AND CONCLUSIONS

Small doses of Pontocaine, combined with 10 per cent glucose, are recommended for spinal anesthesia in selected obstetric cases, including patients with toxemia, eclampsia or nephritis, with acute or chronic pulmonary infections, with upper respiratory infections or with diabetes and those who have recently eaten. Uterine pain is abolished if the anesthesia reaches above the level of the eleventh thoracic segment. Under this type of anesthesia, uterine contractions continue, although they become irregular, less powerful and of shorter duration; hence, the progress of labor is delayed, and intrauterine manipulation is contraindicated. It has no effect on the dilatability of the cervix.

Pontocaine glucose anesthesia was used for the delivery of 150 patients from below and for cesarean section in 23 patients. There were no stillbirths or maternal deaths. The only distressing complication was headache, which occurred in 17 per cent of the patients delivered from below and persisted for as long as six days.

DIABETES MELLITUS AND PREGNANCY

MARTIN NOTHMANN, MD*

BOSTON

THE development of pregnancy in a diabetic woman was a rarity before the discovery of insulin. The cause of the diminished fertility is the severe regressive changes of the ovaries, which manifest themselves in the disappearance of the primordial follicles, with a deficient maturity of the follicles and the lutein bodies. The hypophysis also shows changes from the normal; its weight is decreased and the eosinophilic cells are reduced in number. The basophilic cells show hydropic degeneration. The theory has therefore been proposed that the atrophy of the follicles is due to a decreased function of the hypophysis, namely, a diminished effect of its gonadotropic hormone.¹ In the past, actually only about 5 per cent of all diabetic women became pregnant.

Since the discovery of insulin and its introduction in the treatment of diabetes mellitus, the fertility of diabetic women has distinctly increased and cases of pregnancy and diabetes are observed much more frequently. Therefore, the question of the fate of diabetic pregnant women and the children of diabetic mothers has become considerably more significant.² The mortality was about 45 per cent before the introduction of insulin. It has decreased considerably since then. Nevertheless, it is still estimated as 10 to 17 per cent.²⁻⁵ I can share neither the optimism of some observers nor the pessimism of Bertram,⁶ who states that only in mild cases of diabetes without significant rise of the blood sugar and without tendency to

acidosis should one allow the pregnancy to continue. According to him, every pregnancy should be interrupted with the first sign of metabolic changes, since no one can foresee the outcome for either mother or child. According to Duncan and Fetter,⁷ the need of insulin rises in the first trimester of pregnancy, remains constant in the second trimester, becomes greater in the third and suddenly decreases again after delivery. In my experience, the influence of pregnancy on the diabetic patient is not always the same and cannot be predetermined in any particular case. I have seen diabetic women in whom severe diabetes remained almost constantly unchanged during the whole pregnancy. On the other hand, some pregnant women with mild diabetes suddenly became worse without a demonstrable cause, and rapidly developed coma and died.

Diabetes is even more unfavorable for the unborn child than for the mother. In this regard insulin cannot accomplish much. Before its introduction approximately 60 per cent of such children either were stillborn or died within a few days. Since its introduction the mortality is still about 45 per cent.^{1,8} There are apparently three causes for this failure. The first is because the fetus is often overweight and abnormally large. Bix⁹ found giant infants in 20 per cent of diabetic fetuses, but in only 3 per cent of normal ones. Of 608 children of 155 diabetic mothers, 385 were overweight, 110 had a weight of 4 kg. (8 lb, 13 oz.), 47 of 4.5 kg. (9 lb, 14 oz.), 49 of 5 kg. (11

*Instructor in medicine Tufts College Medical School Junior or assistant physician Boston Dispensary

lb.) and 17 of greater than 5 kg. (11 lb.). Because of the mother's condition or that of the child, rapid delivery may become necessary and may result in birth injury, at times leading to the death of the child. Secondly, these children may die without any demonstrable cause. And, finally, abortion, miscarriage, and stillbirth are frequent. Children with congenital diabetes, however, are extremely rare; Joslin¹⁰ knows of only 3 such cases.

In attempting to account for the high mortality in the children of diabetic mothers, one finds that the greatest danger exists during delivery, which even when normal may cause considerable injury, especially to the blood vessels. All endeavors to deliver such children alive and keep them so must take this factor into account, and avoid even the most insignificant birth injuries. Nothmann and Hermstein¹¹ were the first to recommend prophylactic cesarean section to preserve the life of these children. Others followed.¹²⁻²² In my experience it has resulted in a marked lowering of the mortality, as shown in the 5 cases reported below. At the same time, investigations were made to determine how the mother and fetus influence each other in regard to carbohydrate metabolism.

CASE 1. A 32-year-old woman, with a history of diabetes of 5 years' duration, was admitted to the hospital on February 6, 1930, in diabetic coma, in the 5th month of her first pregnancy. There was no family history of diabetes. In January the glycosuria had increased considerably, and on February 1 the patient began to feel extremely weak. Severe palpitation of the heart appeared, accompanied by dyspnea and pains in the back and the abdomen.

After the patient had regained consciousness in the hospital labor set in, and the pregnancy was interrupted. The fetus was dead. On February 11, she was transferred to the medical clinic, where she remained until March 15.

The urine was sugar-free on a diet of 48 gm. of protein, 70 gm. of fat and 140 gm. of carbohydrates, with 20 units of insulin twice a day.

After discharge from the hospital the patient followed orders strictly and remained under medical control; the urine was examined daily. With the beginning of a sec-

ond pregnancy in September, 1931, the glycosuria again increased, and the dosage of insulin had to be gradually increased to 110 units to keep the patient sugar free on the same diet. In the 8th month of pregnancy she was readmitted to the hospital and remained there until after delivery. During the last month of pregnancy a considerable amelioration of the diabetes occurred, as shown in Table 1. To avoid hypoglycemic reactions a slight glyco-

suria was permitted. The amount of insulin was diminished considerably, and the carbohydrate intake was increased. On May 3, 1932, the patient was transferred to the obstetric department, where during the afternoon labor started. On May 4 she was delivered by cesarean section under spinal anesthesia; the baby was delivered in 10 minutes, and the entire operation lasted 15 minutes. The child, a boy, weighed 9 pounds, 14 ounces. Table 2 shows

the blood sugar of the mother during the last 2 days of pregnancy. During the early part of labor there was a gradual rise of the blood sugar from 142 to 208 mg. per 100 cc. The blood cholesterol was 224 mg. Two hours before delivery the blood sugar was 200 mg., half an hour before 121 mg., at the time of delivery 118 mg. and at the end of the operation 110 mg., the patient having received an additional amount of insulin (20 units) half an hour before delivery. The sugar content of the amniotic fluid was 108 mg., that of the umbilical vein 94 mg. and that of the umbilical artery 82 mg. The blood cholesterol content of the umbilical vein was 85 mg., and that of the umbilical artery 73 mg.

The abdominal incision healed very quickly. In the first few days the baby was put on the mother's breast. On the 14th day the milk dried up and the child, who was thriving, was transferred to the children's department for further care. After delivery the mother's sugar tolerance

became worse, as compared with that of the last weeks of pregnancy, but improved quickly in 2 weeks' time (Table 3).

Of special significance were the results of the examination of the baby's blood sugar in the first days after birth for 4 days it showed a tendency toward hypoglycemia.

FIGURE 1 Blood Sugar of the Baby in Case 1 during the First Days after Birth

values. During this time there was transient unconsciousness on the 2nd day after the birth, when the blood sugar was 45 mg per 100 cc. Only temporarily could it be elevated by injections of glucose. After the 5th day it remained normal (85 mg) (Figure 1).

CASE 2 The patient was a 29-year-old woman who had suffered from severe diabetes for 6 years. During her married life of 6 years, she had two stillbirths, and the third child had died 2 days after delivery from a cephalic hematoma resulting from a birth injury. Her longing for a living child induced me to recommend prophylactic cesarean section. When the patient became pregnant she resolved to follow this advice. In the early months of pregnancy her sugar tolerance decreased. Having been sugar free before she became pregnant on a diet of 64 gm of protein, 140 gm of fat and 120 gm of carbohydrate, with 50 units of insulin daily, she excreted 30 to 40 gm of sugar in the urine daily. The dosage of insulin had to be increased to 70 units daily, upon which the glycosuria was decreased to 3 to 5 gm daily. To avoid a hypoglycemic reaction the insulin was not further increased. In the 7th month of pregnancy clinical examination demonstrated no changes in the sugar tolerance.

At the end of the 8th month of pregnancy the patient was readmitted to the medical clinic. She had felt labor pains the day before. Large amounts of acetone bodies were found in the urine, also 30 to 40 gm of sugar. The patient was therefore transferred to the obstetric clinic and delivered by cesarean section. The baby, a boy, weighed 7 pounds, 1 ounce, and remained alive. The blood sugar taken during the operation was 132 mg per 100 cc. At the end of the operation it was 120 mg and the blood cholesterol was 214 mg. The sugar value of the amniotic fluid was 104 mg, that of the umbilical vein 93 mg and that of the umbilical artery 86 mg. The cholesterol in the umbilical vein was 78 mg and that in the umbilical artery 58 mg.

The baby was breast fed for 18 days, when the mother became ill with mastitis. The milk dried up several days later. After delivery and during lactation a considerable improvement in sugar tolerance was noted in the mother. On a diet of 66 gm of protein, 155 gm of fat and 150 gm of carbohydrate, with 60 units of insulin daily, she was sugar free. The fasting blood sugar was 188 mg. The

baby's blood sugar showed a tendency to hypoglycemia for 5 days (Table 4), and was only temporarily increased by injections of glucose.

CASE 3 The patient was a 24-year-old primipara who had suffered from diabetes for 2 years. She had had only dietetic treatment. In the 8th month of pregnancy large amounts of ketone bodies were found in the urine without a demonstrable cause. On admission to the medical clinic the blood sugar was 286 mg per 100 cc, 1.25 gm of acetone and 6.64 gm of oxybutyric acid per 100 cc were found in the urine, and 0.15 gm of acetone and 0.69 gm of oxybutyric acid in the blood. A living child was delivered.

by prophylactic cesarean section, the baby, born in the middle of the 8th month, weighed 5 pounds, 5 ounces. The blood sugar of the mother at the end of the confinement was 124 milligrams per 100 cc., the sugar of the amniotic fluid was 110 mg that in the umbilical vein 92 mg and that in the umbilical artery 82 mg. The mother's blood cholesterol was 302 mg per 100 cc. Tables 5 and 6 demonstrate the values of the blood sugar of the mother during the confinement, and of the baby for several days after delivery.

The patient recovered very quickly after the operation. The breast feeding had to be stopped after a few days because of lack of milk. The diabetes improved rapidly after delivery. Fourteen days after delivery 10 units of insulin was needed daily. A week later the injection of insulin was stopped.

The baby developed icterus neonatorum 2 days after birth; this disappeared 8 days later. Table 7 shows the cholesterol values from the birth until the recovery from the jaundice.

CASE 4. The patient was a 32-year-old woman with severe diabetes of 7 years' duration. Four years previously a precomatose condition had developed. She had married

the child had spells of unconsciousness, which were promptly relieved by injections of glucose. The blood sugar on the 2nd day of life during an attack of unconsciousness was 43 mg. per 100 cc. The blood cholesterol was 66 mg. Detailed investigations of the metabolism could not be made.

CASE 5. The patient was a 28-year-old woman who had had diabetes since the age of 18. She married at 24 and at 26 had a miscarriage. She was delivered by prophylactic cesarean section in the ninth month of pregnancy. The child, a girl, weighing 5 pounds, 10 ounces, sank into transient unconsciousness on the 3rd and 5th days after delivery. In this case also, injections of glucose were given

with quick response. The blood sugar of the mother during labor, 1 hour after the injection of 15 units of insulin, was 125 mg. per 100 cc. The sugar of the amniotic fluid was 98 mg., the blood sugar in the umbilical vein

90 mg. and that in the umbilical artery 85 mg. The blood sugar of the baby during her unconsciousness was 38 mg. The blood cholesterol of the mother on the day of confinement was 225 mg. per 100 cc. The blood cholesterol of the baby at the same time was 74 mg. and on the 3rd day of life 68 mg.

DISCUSSION

The five cases described are remarkable from different points of view. The influence of pregnancy on the diabetes of the mother cannot be predicted with any certainty. In Case 1 the first pregnancy ended with diabetic coma, whereas in the course of the second pregnancy a remarkable improvement of the sugar tolerance was noted toward the end of the pregnancy. In Case 2 the patient showed considerable increase in the severity of the diabetes at the end of the pregnancy. Case 3 showed, without a marked increase of glycosuria, an alarming increase of the ketone bodies in the blood and urine with the end of the pregnancy. Although others have reported improvement of the sugar tolerance at the end of the pregnancy, I can record only one such case, namely, Case 1 in the second pregnancy. In the other pregnancies the contrary was noted. At about the end of pregnancy a diminished sugar tolerance appeared. Since it is known from the investigations of Carlson and Ginsburg¹³ and Pack and Barber¹⁴ that internal secretions of the pancreas can penetrate through the placenta, it might have been expected that the fetal pancreas would help support the metabolism of the mother. But evidence of such effect could only be supposed in the second pregnancy of Case 1. This aid was not sufficient to compensate for depression of the tolerance caused by the pregnancy itself.

In Cases 1 and 2 the mothers nursed their babies, one of them only for a short time. Aggravation of the diabetes by the lactation could not be observed. On the contrary, in Case 1 considerable improvement began during childbirth, as in some of Wilder's patients.²

The observations made on the carbohydrate metabolism of the babies are of particular interest.

The blood sugar level showed a tendency to descend to hypoglycemic values several days after delivery. Amounts between 45 and 70 mg per 100 cc. were repeatedly observed during a single day. Similar amounts were also noted by Randall and Rynearson.²² Three babies had spells of unconsciousness several times during the first days of life. This was promptly relieved by glucose injection. In two cases a normal blood sugar level was attained only five days after birth. Crevel¹⁸ states that the fasting blood sugar of children of healthy mothers may decrease to extremely low values in the first month of life, and Schretter and Nevinsky¹⁶ have shown low levels during a fasting state in the first days. On the other hand, Rowley,¹⁷ Morris¹⁸ and, recently, Helwig¹⁹ have found the blood sugar level of the babies of diabetic mothers to be not abnormally low. Crevel points out that in those cases in which he had found extremely low blood sugar values no clinical evidence of hypoglycemia ever appeared. Therefore, it is remarkable that repeated unconsciousness has been observed in three cases among those described here. It is also noteworthy that the babies of diabetic mothers seem to differ from other children, since the tendency of the blood sugar to diminish to very low values was again noted a short time after an injection of glucose.

The low blood sugar levels repeatedly noted may be explained by an overfunctioning of the pancreas of the children of diabetic mothers. The second of my patients gave birth to a living baby in her third pregnancy, but it died in a few days as a result of birth injury. I had the good fortune to obtain an examination of the pancreas of this child by Heiberg.²⁰ The gland weighed 5 gm., and the islets of Langerhans were well developed. Nakamura,²¹ who inspected pancreases in different periods of life, found the weight of this organ to be 14 gm. in a baby who had lived only one day, and 15 gm. in a baby four days old. The gland of a baby of six days of age weighed 14 gm., of seven days 15 gm., and of eight days 18 gm. The weight of 5 gm. was not attained till the third to fifth month of life. The pancreas in Case 2 was therefore three times the size of the gland of the average newborn child. It is assumed that the hypoglycemic state of the children of diabetic mothers is due to the hypertrophy of the baby's pancreas. The fetus nourished by the blood of the mother has a permanent surplus of carbohydrate in the form of sugar that she is unable to burn. This excess leads to hypertrophy of the gland and to an increased production of insulin. The increased supply and utilization of the carbohydrates offered by the mother probably ac-

count for the frequently observed fact that the children of diabetic women are extremely big and excessively fat. In the milder cases of diabetes, the increased amount of insulin produced by the fetus seems to be sufficient to improve the condition of the maternal carbohydrate metabolism, and in the first days after birth leads to the hypoglycemic state of the baby, as described above.

Recently Helwig¹⁹ has examined the pancreases of children of diabetic women and has found, in the vast majority, amounts of pancreatic tissue considerably larger than those in the children of nondiabetic mothers. Of 9 cases examined he apparently found in 3 a normal number of islets of Langerhans. He states that in the first case—that of a fetus in the sixth month—the gland weighed 0.8 gm. The pancreas in the second case—that of a fetus in the seventh month—weighed 1.2 gm., and the gland in the third case—that of a fetus of eight months—weighed 5 gm. Considering that, according to Nakamura,²¹ the pancreas of a child born at full term weighs 12 gm., and that it attains a weight of 5 gm. only after the third to the fifth month of post partum life, one must conclude that these three pancreases were abnormally heavy.

Since the hypoglycemia disappears after a few days, one may assume that the overproduction of insulin in the baby of the diabetic mother ceases, and that the islets of Langerhans in the pancreas become adjusted to the needs of the organism.

The cholesterol of the diabetic pregnant women was found to be increased, as is generally shown in the literature. Although some of the patients suffered from severe diabetes, the severity seemed to have no particular influence on the cholesterol values. I found in only one case a cholesterol level of over 300 mg per 100 cc. Four of the 5 babies had cholesterol values between 58 and 74 mg. Joslin¹⁰ also states that in newborn babies of diabetic mothers the cord blood cholesterol has ranged from 50 to 65 mg.

The cholesterol is highest in the maternal blood, lower in the umbilical vein and lowest in the umbilical artery. In only one baby was there a cholesterol level of 162 mg per 100 cc. in the umbilical artery, which is extremely high in this period of life. In this case the cholesterol in the umbilical artery was higher than that in the umbilical vein. On the second day after birth this baby developed an icterus neonatorum that disappeared about the tenth day of life. On the third day, shortly after the beginning of the icterus, the cholesterol was 187 mg., on the eighth day it was 126 mg. and on the twelfth day, after the jaundice

had disappeared, 95 mg. per 100 cc. The mother had the highest cholesterol level among the pregnant diabetic patients. But it is unlikely that the high level of the child was inherited from the mother, because the cholesterol of the umbilical artery was higher than that in the umbilical vein and because the baby's cholesterol continued to increase in the first days of its life. Perhaps the high cholesterol should be considered the first sign of the jaundice that developed later.

The observations here described were made during the course of several years. The children developed well and continued to be healthy. The prophylactic cesarean sections were undertaken in patients who had had stillbirths, miscarriages or living children who died a few days after birth. They resulted in the birth of living, healthy children. Considering the extremely high mortality of children born of diabetic women allowed to go to the normal delivery, it is fair to assume that cesarean section as a prophylactic measure offers a more favorable prognosis. Among five children thus delivered no mortality was noted.

SUMMARY

Five diabetic women with a past history of several abortions and stillbirths were successfully delivered by prophylactic cesarean section.

The high mortality rate of children of diabetic mothers may be decreased by this procedure.

The influence that pregnancy will have on the diabetes of the mother cannot be predicted in any case, in spite of careful treatment. In the same patient, pregnancy at different times may take a very different course.

A state of hypoglycemia in babies during the first days of life sometimes accompanied by periods of unconsciousness is described. The cause of this condition is the hypertrophy and overfunction of the pancreas.

The cholesterol level of the newborn babies ranged from 58 to 74 mg. per 100 cc. Only one baby had a value of cholesterol of 162 mg. This baby later developed an icterus neonatorum.

Considering the extremely high mortality rate of the fetuses and children of diabetic women, prophylactic cesarean section offers a favorable outlook. Therefore, this procedure is recommended to save the life of the endangered fetus.

MEDICAL PROGRESS

THE PHYSIOLOGIC AND THERAPEUTIC EFFECTS OF HYPOTHERMIA*

JOHN H. TALBOTT, M.D.†

BOSTON

COOLING of the superficial layers of the skin has been employed as a physiotherapeutic procedure for countless centuries. Shivering accompanies the sensation of "coldness," and the subject may complain that he is "freezing." There is not, however, a significant lowering of the internal temperature of the body, and except in certain unusual circumstances, the depression rarely exceeds 2 or 3°F. This minor variation stands in sharp contrast to the heroic depression of body temperature (10 to 20°F.) employed recently in the treatment of certain pathologic conditions.

A general lowering of the body temperature was described in the lay press less than two years ago as another procedure useful in the treatment of patients with cancer, and the most optimistic reports alluded to it as "another cure" for cancer. The terms employed in describing the treatment included "freezing," "frozen sleep," "hibernation," "refrigeration" and "cryotherapy." An objection may be raised against the use of each of the terms. "Freezing" and "frozen sleep" are misnomers. No part of the body is frozen; in fact, during most of the treatment the body is exposed to temperatures considerably higher than 32°F., and the purpose of the procedure is to lower body temperature generally, meanwhile exercising great care to avoid freezing any tissue. Fay¹ prefers the term "hibernation" for a general lowering of the body temperature, and "refrigeration" for local cooling. Vaughn² has chosen "experimental hibernation," and Gerster³ and Sauer,⁴ "cryotherapy." Hibernation is a more acceptable term than freezing, but it is not ideal. Physiologic hibernation is peculiar to certain animals only and not to man. Furthermore, in the hibernating state of animal life the body temperature falls to within a few degrees of that of the environment. In the procedure under discussion, the temperature differential between body and environment is from 20 to 50°F. Cryotherapy could be rejected on two counts. If one wishes to anglicize Greek roots, the composition would be cryotherapy⁶ rather than

cryomotherapy. Secondly, one's interest in the effect of low temperatures might well extend beyond its therapeutic possibilities. It is believed that the nomenclature would be more accurate if "hypothermia"⁶ were selected to describe the procedure. It is a scientific term and is not medical jargon. It will be retained in this report wherever it is convenient to refer to a lowering of body temperature.

The initiation of interest of Fay and Henny⁷ in low temperatures was associated presumably with the observation that primary and metastatic cancer rarely involve the parts of the body where reduced temperatures prevail,⁸ that is, reduced as compared with the organs and portions of the body where optimal high temperatures prevail. Thus the extremities are rarely the site of neoplastic tissue and enjoy a low temperature in contrast to the breast, which has a high temperature and is involved frequently with cancer. In pursuing this subject, Smith and Fay⁹ investigated the effect of temperature on the growth and development of the chick embryo. Exposure of eggs to temperatures that varied between 85 and 95°F. for from two to four days at the beginning of the incubation period—the remainder of the incubation proceeding at the optimal temperature (100.5 to 101.0°F.)—resulted in the retardation of growth and the appearance of regressive changes. Developmental malformations were equally prevalent.

In the first clinical report of these authors,⁹ hypothermia was reported to be extremely useful in the treatment of cancer. After a relatively short period of trial,—approximately two years,—this statement has been rigidly qualified. Hypothermia is not recognized as a cure for cancer at present by even the most optimistic of its proponents. It does have a place, however, in the treatment of a selected group of patients suffering from this malady. Furthermore, a study of the physiologic changes associated with a lowering of body temperature may clarify certain problems concerning carbohydrate metabolism, conduction of the nerve impulse, mental processes, the cardiovascular system, the function of the kidneys and the heat regulatory mechanism. Lastly, hypothermia may find extensive application in the rapidly expanding

*From the Medical Clinic of the Massachusetts General Hospital and the Fatigue Laboratory, Harvard University.

†Associate in Medicine, Harvard Medical School, assistant physician, Massachusetts General Hospital.

field of general medical therapeutics. It seems opportune, therefore, to present this progress report.

The majority of the patients treated by hypothermia reported by Smith and Fay⁹ were suffering from inoperable and frequently metastatic cancers. The internal temperature of the body was reduced about 10°F. by exposing the nude anesthetized patient to a bed of cracked ice. The ice was removed subsequently, and general hypothermia was maintained for twenty-four hours or longer by keeping the environmental temperature below 60°F. Certain impressive results were noted. In every case there was a prompt reduction in pain. In many patients the reduction became complete and persisted so for several weeks. This is of particular interest because many had required from 5 to 10 gr. of morphine daily for relief of pain, and several had been referred to a neurosurgical service for chordotomy. By the continued use of local cold for several weeks following the general hypothermia, it was possible to avoid surgical intervention, and in most patients to prevent the subsequent return to large doses of sedatives.

Furthermore, there has been regularly a rapid, gross, measurable decrease in the size of the lesion within twenty-four to forty-eight hours. In a few cases, this has been as much as 50 per cent. This decrease in size had progressed steadily during the course of treatment. There has been a general improvement in the patient's condition, with a gain in weight, a better appetite and a change for the better in the mental state. There has regularly developed a notable tendency toward healing of previously intractable ulcerative cutaneous lesions and fistulous tracts. It must be remembered that these patients had all been given up from the standpoint of the more orthodox methods: operation and irradiation. There has been a marked retardation in recurrences, and the rate of growth during recurrences has been definitely diminished, as shown by careful studies by one of us (Smith) of several biopsy specimens taken at intervals during the course of treatment. In at least two instances there has been complete disappearance of the local lesion.⁹

This very encouraging report has been modified¹ recently without lessening the significance of the earlier contribution.

Before proceeding with the topic under consideration, it may be of interest to inquire about the lowest internal temperature that man can tolerate. Contrary to previous medical teachings, it probably lies somewhere between 70 and 75°F., and not between 90 and 95°F. In 1875 Reincke¹⁰ reported the findings on five inebriated persons who had accidentally been exposed to cold. The rectal temperatures after admission to the hospital of the two who recovered were 75.2 and 86°F. respectively. The three who did not recover had temperatures of 79.5, 80.6 and 83.1°F. respectively. Nicolaysen¹¹ observed a rectal temperature of

76.4°F. in an acutely intoxicated patient, who recovered. During therapeutic reduction of body temperature, Fay¹ observed a minimum of 74°F. in one patient who did not survive treatment. Under similar circumstances Dr. Kenneth J. Til- lotson and I⁶ have observed a patient whose rectal temperature reached 74°F. at one time and whose temperature remained below 80 for more than ten hours. A second patient in our series had a recorded rectal temperature of 75°F. Recovery was uneventful in both. It is possible that these are above the critical level under ideal conditions, that is, in a hospital under close medical supervision, but they are probably not far above this level.

Homoiothermic animals (nonhibernating mammals), such as the cat,¹² the domestic rabbit¹³ and the monkey (*Macacus rhesus*),¹⁴ on the other hand, have been known to live following a reduction of body temperature to as low as 56 or 60°F. It is not certain whether this represents a real physiologic difference between lower animals and man, or whether it is related to the greater risk that may be taken with animals and the sacrifice of many to achieve an extremely low temperature in a few. The heat regulatory mechanism presumably ceases to operate below 75°F. in animals, and the continued fall in body temperature proceeds at the same rate as that in a dead animal under similar circumstances.¹² If the animal is then warmed, the thermal regulatory mechanism begins to assert itself at approximately 75°F. In the hibernating animal, the body temperature may approach 32°F. without causing death.

For additional information concerning hypothermia in human beings one must be satisfied with a very limited bibliography. There are several explanations for this. The employment of general hypothermia in the practice of medicine is recent. Only a few hospitals have been actively interested in the problem, and the number of workers in the field is small. The induction and maintenance of general hypothermia require considerable technical equipment and professional attention, and are not without danger to the subject. Because of the unavoidable risk associated with each treatment, it is probably desirable that only a few hospitals explore the therapeutic possibilities of hypothermia for the present. If a hazardous procedure such as this were mishandled, it might well fall into unwarranted disrepute before the facts and fallacies accompanying it were clearly defined.

INDUCTION AND MAINTENANCE OF GENERAL HYPOTHERMIA

The methods employed by the various investigators for the preparation of the patient and the

induction of hypothermia are similar. Written permission to conduct the treatment should be obtained from the patient or the legal guardian. A laxative may be administered the night before induction, followed in eight hours by an enema. It has seemed preferable to take patients who have not eaten for twelve hours, but probably this is not imperative. Three or more grains of Nembutal are given intramuscularly twenty minutes before the patient is placed in a cold environment. The sedative effect of Nembutal is desirable, but its most important action is on the heat regulatory mechanism. A drop in the body temperature is achieved without difficulty if the patient is prepared with Nembutal; otherwise, it may be very difficult, other aspects of the treatment being equal. When the stage is set, the patient is prepared finally with an anesthetic that is effective over a relatively short period of time. For this, from 0.5 to 0.7 gm. of Evipal, given intravenously, has been very satisfactory in my experience. As soon as the anesthesia has achieved its full effect, a rectal thermocouple* is inserted, and the patient is placed nude in an environment of approximately 32°F. Either especially constructed blankets† or cracked ice may be employed for the induction of hypothermia. Within an hour, the anesthetic effect of the Evipal has for the most part worn off, and simultaneously the body temperature decreases. The anesthetic property of the cold^{13, 16} usually obviates the necessity for further intravenous anesthesia or sedative. All the patients whom Dr. Tillotson and I have studied have been relatively quiet without further anesthesia when the body temperature has been maintained below 90°F. During the induction of hypothermia, the temperature drop may be as rapid as 3°F. an hour, or as delayed as 0.5 an hour. When the desired minimal body temperature is approached, the environmental temperature is raised. Since an internal body temperature less than 80°F. approaches the critical level, we have endeavored to maintain a working range for internal temperature between 80 and 90°F. By alternately lowering and raising the external temperature, the internal temperature may be controlled within a range of 2 to 3°F.

In the earlier studies of Fay and Smith, the period of hypothermia did not exceed three days. The term of treatment was extended as the work progressed and as the body appeared able to tolerate longer sessions. If one wishes to refer to a "record," I have not found any reference that exceeded an eight-day treatment.⁴ The body tem-

perature was maintained at a level of approximately 85°F. the greater part of the time. It is the current belief that regressive changes in metastatic tissue associated with general body temperatures below 90°F. are not evident until a temperature as low as this has been maintained for a minimum of five days. In some patients intermittent periods totaling more than three hundred hours must be tried. The failure of Vaughn² to duplicate Fay's results may be attributed in part to the duration of treatment. Vaughn induced hypothermia in 6 patients, and maintained hypothermia for an average of not more than thirty-six hours. The treatments were not repeated. He stated that "the procedure was hazardous and not justifiable in the treatment of hopeless metastatic carcinoma." Fay has supervised approximately one hundred and seventy-five treatments since he began them in December, 1938, and believes that further study is indicated. I concur in this belief.

Fay⁷ has deemed it advisable to go through a trial treatment of not more than twenty-four hours to gather information concerning the reaction of the patient to the procedure. Undoubtedly, this is important for patients who have metastatic cancer or who are older than forty. It is probably unnecessary for patients who are in reasonably satisfactory physical condition, and who are younger than forty. Following the initial treatment there may be one or more additional periods of from two to four days each. The intervals between successive treatments may be as short as two or three weeks. It is unknown just how many times the treatment may be repeated or whether many permanent harmful effects follow a large number of successive treatments.

The patients, usually, are drowsy and stuporous during the treatment, but they are not comatose unless they are sedated heavily or unless the body temperature goes below 80°F. Some observers allow the subjects to eat solid food from time to time. In an attempt to collect satisfactory metabolic data in our series, we have preferred to introduce measured amounts of water, salt and glucose by way of a stomach tube. Most patients have tolerated 50 cc. of 5 per cent glucose in normal saline by this route every thirty minutes. Gastric absorption of food and fluid appears to proceed at a normal rate in human beings exposed to cold.¹⁰ In dogs,¹⁷ the emptying time of the stomach decreases slightly.

When it has seemed desirable to terminate the treatment, which usually is an arbitrary decision, the external environmental temperature is allowed to approach 70°F. It has been our experience that a gradual restoration of body tem-

*A continuously recording instrument (Nicromax) is manufactured by Leeds and Northrup, Philadelphia, Pennsylvania.

†Blankets adapted for a continuous flow of refrigerant are manufactured by the Therm-O-Rite Products Company, Buffalo, New York.

perature, that is, not greater than 2°F. an hour, is associated with fewer ominous signs than a rapid rise. Following restoration, most patients show a rise above normal for a short time.

COMPLICATIONS AND MORTALITY

We have observed no serious post-treatment complications. Some of the patients have developed mild edema of the extremities for a few days. No other physical findings have been observed in those who before the treatment were relatively sound physically. Neither an upper respiratory infection, pneumonia nor acute nephritis has appeared in any of our patients. This is of interest when considered together with the observation of Foord¹⁸ that the agglutinin production of rabbits increases following exposure to cold, the increase persisting for as long as twenty-four hours after exposure. Autopsy findings of patients dying from cancer have confirmed the impression that normal tissue is not harmed by general hypothermia.^{19, 20} Furthermore, healing of tissue proceeds uninterruptedly during local hypothermia, with a minimum of scar formation.

Fatalities have occurred within twenty-four hours after treatment. In our series there were two deaths among twenty patients. Both were from cardiac failure, and both occurred during the period of hypothermia. One was probably preventable, the other was not. The first death occurred very early in the series, when the necessity for slowly warming the patient during restoration of body temperature was not appreciated. The second death occurred in a woman suffering from extensive metastases from a primary carcinoma of the breast, scirrhus carcinoma of the stomach, coronary heart disease and morphinism. She was a very poor risk, and hypothermia was considered only as a last resort. She died during treatment after her body temperature had been maintained between 86 and 89°F. for thirty hours. If one discounts this death, the mortality rate in our series is low. This statement is not made, however, to minimize the risk of treatment. The experience of other observers with chronically ill patients is similar to ours. Cardiovascular failure and pneumonia have accounted for most of the fatalities. The development of pneumonia in patients with metastatic cancer in the lungs is sufficiently common to cause rejection of such patients for treatment.²¹

PHYSIOLOGIC AND BIOCHEMICAL PHENOMENA OBSERVED DURING HYPOTHERMIA

Changes in the vascular system develop early; they are profound in magnitude and marked in

their variations from the normal. Following an initial rise of pulse and blood pressure, there is a gradual fall of both until the minimum body temperature is reached. In human beings the heart rate rarely falls below 50 a minute, whereas in nonhibernating animals exposed to cold, it may slow to 14 or 16.¹³ The changes in pulse and blood pressure are associated with a marked vasoconstriction, arterial and venous, which becomes general as the temperature declines. Obliteration of peripheral venous channels, such as may be observed during casual exposure of an extremity to the cold, is noticed first. Drawing of venous blood becomes very difficult and may subsequently be impossible in a person who presents no difficulty at normal body temperature. With continued hypothermia, constriction of the large arteries occurs, and frequently one is able neither to elicit the radial or brachial pulse nor to obtain a blood-pressure reading in the customary manner. The blood pressure and peripheral pulse may be unobtainable for several hours, yet vascular occlusion or thrombosis is not a complication. Blood does flow in the arterial channels, however, because arterial punctures are possible, and in our series furnished most of the samples used for determining the concentration of the various blood constituents.

An increase in the circulation time of venous blood and a decrease in volume of circulating blood are other consequences of prolonged vasoconstriction. The circulation time from arm to leg may be prolonged two or three times over normal.²² Observations of blood and plasma volume have not been reported for man, but in animals Harkins and his associates^{23, 24} have observed a decrease in blood volume. This is the result presumably of the migration of fluid from the vascular channels into the interstitial spaces.

Cardiac arrhythmias, sinus arrhythmia and auricular fibrillation are frequently observed during treatment. The lower the body temperature, the greater the likelihood of the development of an arrhythmia.²⁵ All our patients whose temperatures reached 80°F. developed fibrillation. Digitalis, quinidine and restoration of body temperature are effective in correcting this disturbance. Electrocardiograms taken during hypothermia show fairly constant changes. In a series of 9 patients, Kossman²⁵ noted an alteration in the form of the final ventricular deflection and a prolongation of electrical systole. A high take-off of the T waves and a diphasic T₂ have also been reported. During recovery, the QT interval does not return to normal immediately; in fact, several days may elapse before this occurs. Tomaszewski²⁶ has re-

ported detailed observations on a man, aged fifty-four, who suffered from accidental exposure to the cold, but did not die until after he had been observed for several hours in the hospital. When he was seen first his heart rate was 21 per minute. Before death, the rate increased to 44. The electrocardiogram showed prolongation of the PR interval, low voltage and delayed conduction time. At autopsy, no significant morphologic changes in the heart were detected. In the dog, Otto²⁷ observed inversion of the T waves after chilling of the right ventricle with ethyl chloride, and a high take-off of the T waves after chilling of the left ventricle.

The formed elements of the blood undergo as diverse variations from normal as the cardiovascular system. If the fluid balance is not maintained, hemoconcentration follows with an increase in red-cell count as great as 25 per cent above normal.²⁸ The white-cell count increases several-fold with a rise in the percentage of polymorphonuclears. The percentage of reticulocytes also increases.² The sedimentation rate and the platelet count decrease. Within forty-eight hours after restoration of body temperature, the sedimentation rate returns to the pretreatment level.²⁰

Scattered observations have been made on the chemical constituents of the blood. In view of the statement by Smith and Fay⁹ that renal function ceases during hypothermia, it is of particular interest to inquire into the concentration of non-protein nitrogen of the blood. Vaughn² observed a significant decrease in this constituent in 4 out of 6 patients during treatment. In 2 patients, there was an increase. Bernhard²⁰ observed an increase in 2 patients only, and no change in the remaining 24 of his series. The other constituents that have been studied—calcium, phosphorus, chloride and cholesterol—show no significant change during treatment.

Routine urine analyses for albumin, sugar and formed elements are negative.

Since the hibernating animal has a metabolic rate below normal it seems reasonable to expect that in human beings during general hypothermia a similar depression of this function might be detected. Patients with metastatic cancer who are given therapeutic amounts of sedatives periodically during the treatment show such a depression.²⁰ If the cold alone is relied on for sedation, it is possible that the rate may be unchanged or above normal. A final decision in this matter must await further investigation. Obviously, it is desirable to learn how important an altered oxygen consumption is in the production of the therapeutic and physiologic effects described.

Pupillary reflexes disappear in human beings during hypothermia²¹ as they do in animals¹⁴; crossed tibial reflexes and the absence of plantar response have been observed. The loss of nerve conduction appears to be a direct effect of cooling.²² During recovery a restoration of the abnormal responses occurs.

Hypothermia offers an interesting opportunity for the study of shivering. All patients shiver shortly after exposure to the cold environment unless they are heavily sedated. Fay¹ observed a disappearance of shivering when the temperature fell below 90°F. This has not been our experience with patients who have been given no drugs after the induction anesthesia. We have observed patients to shiver intermittently as the temperature fell to as low as 75°F., just as animals shiver at low temperatures.^{33,34} On the return toward normal temperature, shivering is less violent. There are two explanations for the individual variation in shivering. I am inclined to attribute cessation of shivering in Fay's series to the periodic use of sedatives. Hypoglycemia is another antishivering agent. In the dog, insulin may abolish shivering due to cold.²⁹ It is possible that some patients develop spontaneous hypoglycemia during hypothermia, and shivering is subsequently inhibited.

Burton and Bronk³⁵ noted two types of muscle tremors in the anesthetized cat following cooling. When the rectal temperature fell below 93°F., intermittent and inco-ordinated twitches of single units appeared. A rise of oxygen consumption followed shortly. The response appeared first in the muscles of the head and thorax, then in the superficial pelvic muscles, and lastly in the deep muscles of the extremities. The response of a given muscle increased in regularity by the number of active units, and in frequency from 5 to 12 per second. Later, co-ordinated grouping of discharges appeared and resulted in gross tremors, and shivering (11 per second). A single unit discharged only once in each group. That a similar phenomenon occurs in human beings was mentioned as a possibility by Denny-Brown and his associates.³² Undoubtedly, further study of hypothermia will clarify this matter.

THERAPEUTIC CONSIDERATIONS

General hypothermia has been used for the treatment of several conditions. These include intractable pain, cancer, morphine addiction, leukemia and schizophrenia. The treatment was devised originally for patients suffering from cancer. Although definite regressive changes in undifferentiated cell growth in deep metastatic lesions have not been observed consistently, hypothermia has

a place in the treatment of selected patients suffering from neoplasias. Relief of pain may well be the most important therapeutic gain, and all observers who have reported on the subject are in agreement concerning this effect. So successful has it been that Fay¹ no longer considers narcotics necessary in the treatment of intractable pain and "operative intervention for pain [chordotomy and rhizotomy] has not been required during the past two years."

Approximately two thirds of the patients who complain of pain and who submit to hypothermia experience reasonably prolonged periods of relative or complete freedom. There are several cases in which patients who required several grains of morphine daily for control of pain before treatment became quite free from pain, without opiates, following hypothermia. Systematic relief appears to be independent of the location of the tumor. Pain secondary to new growths of the brain, antrum, buccal cavity, thyroid gland, breast, lung, stomach, sigmoid, rectum, kidney, adrenal gland, testis, prostate, bladder, cervix, vulva or skin has responded. The duration of relief varies. Some patients are helped for only a few days; others may remain symptom free for as long as four months. The effect of cold on pain is noteworthy and clinically important.³⁸ Precisely why the anesthetic effect on the sensory nerves should persist for several months is not understood.

Not only does pain associated with tumors respond, but simultaneously, regressive changes in neoplastic tissue have been evident on microscopic examination. The response of sarcoma is less striking than that of carcinoma. The more undifferentiated the carcinoma, the more rapid is the regressive phenomenon. Primary tumors as well as lymph nodes that have been invaded have undergone diminution in size. In certain patients with tumors of the gastrointestinal tract, the regressive changes have been so extensive that the tumor has sloughed out of the wall of the involved region, with the development, later, of peritonitis.

It is advisable to inquire whether general hypothermia increases the rate of growth of tumor tissue or damages normal tissue. No evidence has been accumulated to suggest that the rate of growth of tumor tissue is accelerated. So long as the temperature is reduced, any effect on growth is retardative. Similarly, it has been shown that significant cell changes in normal tissues are most infrequent.

Probably more important than general hypothermia in the treatment of cancer is the use of local hypothermia. The application of cold locally

in the treatment of tumors was discussed by Cooke as early as 1865³⁹ as follows:

Cold, by means of ice applied with great caution, has its uses. It subsides those occasional inflammatory paroxysms to which scirrhus tumor is prone, and may check the disposition to suppuration, the result of inflammatory action. Its constant use, however, in all states of the tumor is not warranted by experience. The destructive power of this agent is so great, that I have seen the whole breast slough as a result of the prolonged application of ice, and the sloughing, in the instance I refer to, extended through the intercostal muscles into the cavity of the chest.

Recent studies have shown that regressive changes are most obvious when local hypothermia can be carried out at a temperature between 40 and 50°F.²¹ Special fitting coils through which a refrigerant circulates are applied. As observed by Cooke, necrosis of tumor tissue may follow. Rarely, there may be complete disappearance of tumor cells as observed histologically in successive biopsies. It has been observed in some patients who succumbed to the cancer and who came to autopsy that the treated primary site was quite free of tumor cells.

McCravey⁴⁰ has reported favorable results with local hypothermia in 5 cases of carcinoma of the bladder. By marsupializing and exteriorizing the bladder cavity, especially designed metal applicators were enabled to enclose partially the lesion and bladder cavity. In each patient on whom this was carried out, the local bladder tumors were reduced in size or destroyed, all or in greater part, within from six to twelve weeks. The deeper extension of such tumors when it had not been possible to maintain accurately the desired temperature showed regressive changes, but some tumor tissue persisted. In all cases the patient's life was prolonged beyond that expected for a patient not treated with hypothermia.

The phenomenon of regression has been summarized by Smith and Fay.¹⁹

Granular hydropic and fatty degenerative changes may be observed in the cytoplasm of the cells, depending largely on their individual character and origin. In many instances the ratio of nucleus to cytoplasm is so distorted that little evidence of cytoplasmic change can be observed. The cytoplasmic changes are followed by or associated with nuclear degeneration. More frequently pyknotic condensation of the nucleus occurs, ending in actual rupture of the nuclear membrane. It has been our experience, as has already been indicated, that the more undifferentiated such tumor cells are, especially if they belong to the epithelial series, the more rapid and extensive are the regressive phenomena. Histologically, the effects of this physical agent, cold, are not so unlike the effects of that physical agent which has been more carefully studied in respect to cell changes, roentgen radiation.

It is possible that radiation combined with cold⁴¹ might be a more effective agent than either one alone, just as cold renders plant cells more sensitive to radiation.

It is difficult to reconcile these observations of the effect of cold with other experimental observations in the literature, particularly those that concern the behavior of animal tumors. Lambert⁴ showed that cancer cells are more resistant to cold than cells of the normal adult. Aulcr and his associates⁴² exposed the Flexner carcinoma and the Jensen sarcoma of the rat to temperatures as low as 32°F. The tumors were then transplanted. Most of the transplants grew. It was assumed that the tumors formed sporadic cells that were resistant to the cold. Tumor transplants were killed at a temperature from 70 to 98°F were more successful than those maintained at 98°F. Bischoff and his associates⁴³ studied sarcoma No. 180 in 29 mice. The body temperature of the animals was reduced as low as 65°F. No permanent effect on the growth process was noted.

Several patients suffering from leukemia have been treated by hypothermia. Reich²⁸ has reported 2 such cases. One patient was in the terminal stages of aleukemic lymphoblastic leukemia. No changes attributable to the treatment were observed. The second patient was suffering from acute myeloblastic leukemia. The total white cell count decreased from 50,000 to a normal level during each treatment, and remained within the normal range for several days. No change in the differential count—95 per cent myeloblasts—was observed. The diminution in the white-cell count of patients with leukemia is quite the reverse of the process observed in patients who present no disturbance of white-cell economy.² That further investigation of the use of hypothermia in leukemia is indicated seems obvious.

Closely associated with the relief of pain is the treatment of morphine addiction. Patients with cancer who have required large amounts of opiates for relief of pain before general hypothermia have been able to live afterward without such drugs for several months. In others, smaller doses of sedatives than formerly have been required to control symptoms. Similarly, morphine addiction per se has responded to general hypothermia. Most patients require only one period of a few days for a favorable therapeutic effect.

The use of cold in diminishing the undesirable effects of intoxication has been appreciated for some time. This is evident from a description reported in 1803.⁴⁵

A Gentleman of this Island whose name was Weeks, a great votary of Bacchus, was in the practice from fifteen to twenty years, of plunging into cold water

when he rose from his bottle, and of actually going to sleep in a trough full of water, with his head supported on a kind of wooden pillow made for the purpose, above the surface. When he dined abroad and had not the convenience of his own trough he used to strip off his coat, waistcoat, and shirt, and sit exposed in the open air, and in that situation go to sleep, whether it rained or not. And sometimes he went and bathed in the nearest adjoining pond, to which he generally required assistance to be conveyed. The effect of this practice was, that instead of experiencing debility, lassitude, headache, and nausea, he found himself on awakening cheerful and refreshed, and free from all the effects of intoxication. In the year 1789, during one day abroad he got alternately drunk and sober three times before midnight each time recovering his sobriety by himself by immersing himself, and sleeping in cold water, and on awakening returning to the company. The last time after supper, he was so immoderately intoxicated, that he insisted on his companions undressing him and conveying him themselves to the pond. They carried him accordingly in a chair, and set him up to the chin in water, where he continued upwards of an hour, a person supporting him. I heard this last circumstance from a gentleman, one of the party, whose veracity may be entirely depended on.

At home, however, he used, as I have already mentioned, a trough made for the purpose, with a bench in it as a pillow, having been nearly drowned when sleeping in his pond, from the negro who was appointed to watch him, having himself fallen asleep. In this watery bed he would sleep, one, two, three, or even more hours, experiencing always the greatest refreshment. His wife and family, when they wished him to change his quarters used to draw out the plug, and let the water run off when he awoke and humorously complained of the loss of his bed clothes. At length this expedient began to lose its effect in rousing him and one time, he continued to sleep in an empty trough. In consequence of this, he was seized with extreme rigors and chills, followed by a severe attack of rheumatism, which affected him a long time, and made him desist from the practice in the future. But to the end of his life he was in the habit of sitting, when intoxicated, with his clothes open, and sometimes quite naked, exposed to the wind and the rain. This extraordinary character died of apoplexy about three weeks ago, aged sixty three.

In recent months Dr. Tillotson and I have studied the effects of hypothermia on patients suffering from schizophrenia.⁶ Ten patients were studied, 4 of whom were subjected to two or more periods of general hypothermia. Most of the patients had been treated previously with insulin or Metrazol, or both, without benefit. All those who were older than thirty years and who had been confined to a mental hospital for a long time, showed little or no prolonged alteration in their mental symptoms. On the other hand, of those who had been sick for less than three years all except one showed a recrossing alteration in their clinical courses. In 4 patients the improvement has been striking and continuous for six months. In 3, marked temporary improvement was noted.

It is appreciated that the total number of patients is small, but with promising results, continued efforts are justified.

OTHER CONDITIONS TO BE INVESTIGATED

The conditions discussed above may serve little else than to introduce the subject of therapeutics by hypothermia. The field of possibilities for the future may be large. The reader, undoubtedly, has visioned benefit in such disturbances as Hodgkin's disease, lymphogranuloma venereum, subacute bacterial endocarditis, parasitic diseases, undulant fever, chronic arthritis, acquired syphilis, acute toxic psychoses, tetanus, multiple sclerosis, intractable migraine and encephalitis.

SUMMARY

Observations on the experimental reduction of the internal temperature of the body as well as local application of cold constitute the basis of this report. A discussion of hypothermia is timely because the physiologic changes and therapeutic implications associated with it have begun to be studied systematically only of late. During general hypothermia the internal body temperature may be lowered to 75°F. with subsequent recovery. It may be maintained continuously between 80 and 90°F. for as long as eight days. If local application of cold is employed, a circumscribed area of the body may be maintained between 40 and 50°F. for several months without damage or destruction of normal tissue.

Relief of pain is probably the most important single effect of general hypothermia in patients with metastatic cancer. Regressive changes in tumor tissue have been reported following prolonged general hypothermia, but are observed more constantly following prolonged local hypothermia. Other conditions that have appeared to benefit from general hypothermia include morphine addiction, leukemia and schizophrenia.

It should be appreciated that knowledge in the field of hypothermia is most fragmentary and that until a large amount of painstaking labor is expended, a full and comprehensive understanding of all the related facts will not exist.

TRACY B. MALLORY, M.D., *Editor*

CASE 27071

PRESENTATION OF CASE

A sixty-three-year-old unmarried woman entered the hospital complaining of abdominal pain and jaundice.

Since the patient was drowsy and not cooperative, the history was obtained largely from her relatives. It appeared that from early womanhood she had suffered from "bilious attacks" characterized by indigestion, nausea and vomiting. In more recent years the attacks had become more numerous and were accompanied by upper abdominal pain, which the patient was unable to localize accurately. These episodes were not accompanied by jaundice, chills or fever. Two weeks before admission she suffered a severe attack of upper abdominal pain accompanied by persistent nausea and vomiting, two chills and fever. She noticed that her stools were light in color and her urine dark, and one week after the onset of abdominal pain, marked jaundice appeared, with severe pruritus. At the time of admission the jaundice was subsiding, but the nausea persisted. Her appetite had always been good until the onset of her present illness.

It was stated that the patient had had jaundice once as a child and rheumatic fever at twenty five with "a little heart damage," but no recurrence. When the patient was fourteen, her mother died of what was said to be "consumption."

On examination the patient was a well-developed, obese woman whose skin was dry, scaly and markedly jaundiced. The pupils were small and regular, and reacted to light and accommodation, the scleras were jaundiced. The skin of the abdomen, flanks and upper thighs was excoriated, and contained a number of slightly raised, red dish papules. There was a diffuse reddening of the nasopharynx, with a mucopurulent exudate. Examination of the heart was negative; the blood pressure was 135 systolic, 68 diastolic. There was slight dullness to percussion, with many fine rales on auscultation at both lung bases. The abdomen was obese and pendulous, and a tender, vague mass was palpated in the right upper quadrant, extending medially into the epigastrium. Rectal examination was negative.

The temperature was normal, the pulse 90, and the respirations 30.

Examination of the urine showed a + test for albumin and a + bile reaction, with 20 white blood cells per high power field.

Examination of the blood showed a red-cell count of 4,200,000 with a hemoglobin of 11.9 gm. (photoelectric cell technic), and a white-cell count of 61,000 with 98 per cent polymorphonuclears. A van den Bergh showed 40 mg. of bilirubin per 100 cc. of serum, biphasic. The prothrombin time was 31 seconds (normal, 16 seconds), and the hematocrit reading 39.4 per 100 cc. The non-protein nitrogen of the blood serum was 130 mg. per 100 cc., the serum protein 5.6 gm. per 100 cc., and the blood chlorides 966 milliequiv. per liter.

X-ray films of the abdomen, taken with a portable machine, were not entirely satisfactory because of the patient's size, but no definite abnormalities were noted. The right side of the diaphragm was probably elevated.

The patient was given intravenous fluids and one 500 cc. blood transfusion. On the third hospital day the white cell count had fallen to 41,800, and the nonprotein nitrogen to 100 mg. per 100 cc., but the prothrombin time had risen to 43 seconds. Seven days after admission the temperature was 100°F. and the following day had risen to 102. On the ninth hospital day the patient was operated on. A 15 cm. incision was made in the right upper quadrant of the abdomen. Numerous fresh adhesions were encountered, and there was a sudden gush of thick, greenish black bile from what was presumably an old, friable, gangrenous gall bladder. Everything was gently palpated, and no stones could be felt. Further exploration was deemed inadvisable, and one rubber tube was sewn into the gall bladder and a cigarette wick placed beside it. The wound was closed carefully, using silk for the fascia.

Postoperatively the patient's condition remained precarious, the temperature averaging 100.2°F.; the wound drained small amounts, never more than 15 cc. of bile-stained fluid. She was given daily intravenous injections of 1500 cc. of 75 per cent glucose in physiologic saline solution and many blood transfusions. Five days postoperatively she had a chill and complained of a sharp substernal pain. On examination her color was ashen, and she responded poorly. The temperature was 104°F., the pulse 122, weak and irregular; the blood pressure was 96 systolic, 60 diastolic. Respirations were 27, and were groaning and shallow. There was bronchial breathing with dullness at the left base, and bilateral basal rales. The patient was placed in an oxygen tent, but death

occurred the following day. Latterly the nonprotein nitrogen rose to 110 mg. per 100 cc., and the serum van den Bergh dropped to 6.4 mg. of bilirubin per 100 cc.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: May we see the x-ray films?

DR. RICHARD SCHATZKI: The portable films are very unsatisfactory, as the record states. There is a little more to be seen on the films than stated in the record. There are areas of atelectasis in both lower lung fields. One cannot see the spleen. There are no visible gallstones, but gallstones would have to be fairly large to show in a film of this quality.

DR. MCKITTRICK: Thank you. The films do not confuse me more than the written report, and that is always a help.

Here is the story of a sixty-three-year-old woman the early part of whose history I cannot make much out of and have to disregard. I do not know what is meant by "bilious attacks." As I listen to patients complaining of "biliousness," they are just as apt to use this term for episodes of migraine as for gall-bladder attacks. In more recent years the attacks became more frequent. There were no chills, jaundice or fever, but the patient did have abdominal pain at about that time, and it is possible that the bilious attacks were attacks of pain. Otherwise she was perfectly well until two weeks before admission to the hospital, and we are therefore dealing with an acute process, consisting of a sudden severe attack of upper abdominal pain accompanied by persistent nausea and vomiting, two chills and fever. The stools became light in color and the urine dark, and one week after the onset of abdominal pain, marked jaundice with pruritus appeared. If one takes the recorded facts,—progressively frequent attacks of indigestion, some with pain, culminating in a sudden severe attack of pain, chills, fever, light-colored stools, dark urine and jaundice,—then I think one might rightfully assume that the patient had gallstones, that one or more stones had dropped into the common duct, and that she had in addition a cholangitis.

On physical examination she was found to be very obese, to be severely jaundiced, to have excoriations secondary to the itching that goes with jaundice, and to have a big mass, palpable in the right upper quadrant, which extended medially into the epigastrium. The temperature was normal, and the white-cell count was 61,000 with a little secondary anemia. Presumably there was no blood dyscrasia because 98 per cent of the white

cells were polymorphonuclears. She had a very high bilirubin: 40 mg. There was a rapid prothrombin time, an elevated nonprotein nitrogen, a slightly lowered serum protein, and a normal blood chloride. The picture at this point becomes confusing, because she became drowsy and the nonprotein nitrogen rapidly climbed to 130 mg. per 100 cc. Despite the normal temperature, the white-cell count remained notably high. The urine showed a + test for albumin. I am impressed with the rapid prothrombin time only two weeks after the onset of an apparently acute process. It seems to me that such a patient must have something more than can be explained on the basis of a common-duct stone, with or without an acute gall-bladder condition. I am inclined to believe that the drowsiness, the high nonprotein nitrogen and the early development of a rapid prothrombin time are evidences that, in addition, she must have had a good deal of liver damage due to acute hepatitis or perhaps hepatic insufficiency.

I shall assume that she had gallstones, but that that is not the whole story. A number of other conditions must be considered, but there is not time to discuss all of them in detail. The disproportion between the temperature and white-cell count in a patient who is so sick so soon after the onset of symptoms makes one think of acute pancreatitis in association with a common-duct stone. However, the evidence is so much in favor of hepatic insufficiency and the findings are so definitely right-sided that I should prefer some other explanation. A pylephlebitis is, I presume, a definite possibility, but I should not be able to make this diagnosis. I should operate on the assumption that she had gallstones. I believe that she had a stone in the common duct and cholangitis, and for the reasons already described, severe intra-hepatic disease. To explain the mass in the right upper quadrant I should have assumed a large, distended gall bladder, but in view of the additional information obtained at operation there must have been a perforation, and this probably represented an abscess in relation to the gall bladder and adjacent structures. Even though no stones were found at operation, I assume that they were present.

I do not see how one can be certain why the patient died so suddenly. She had a rapid prothrombin time, but she had a lot of transfusions, and one would have thought that the transfusions would have controlled any bleeding tendency. She might have had a pulmonary embolus. I do not think that was the cause of her death. Progression of the biliary-tract disease might well have been enough.

I should hate to give the impression that I have any confidence at all in my interpretation of these findings. I simply believe that the patient had gallstones, in addition to something more to explain this picture, and I should like to put all the emphasis on the liver. Whether or not she had pancreatitis I do not know, but I doubt it.

DR. HORATIO ROGERS: If you account for the mass on the basis of abscess, you still leave the discrepancy between the temperature and white-cell count not accounted for.

DR. MCKITTRICK: Yes; I have not been able to account for it entirely. Of course this patient was not absolutely afebrile; the temperature was slow to climb, but did start up at the end of a week in the hospital.

DR. RICHARD WARREN: Dr. Richard H. Miller operated on this patient but could not be present today. We went through the same course of reasoning as Dr. McKittrick, but without arriving at such a concrete decision. She was sent in with a diagnosis of stone in the common duct, and for the first day or so, we assumed that that was what she had. The more we thought the story over, — the normal temperature, the elevated white-cell count and the fact that she had bile in the stools, — the more the whole preoperative picture confused us. The mass, which was not palpable when she first arrived, appeared during the nine days preceding operation. The question was whether to operate and when I might say, in justification of the operation, that the prothrombin time had dropped to 20 seconds by the day of operation and the nonprotein nitrogen to 60 mg, so that she was not quite so sick as the data in the abstract indicates. At operation the mass that we came down upon was assumed at first to be the gall bladder, but it was not in the gall-bladder fissure, because the falciform ligament was definitely coming out in that area. Since the patient was in such poor condition, and since bile drained freely from this cavity, a tube was inserted in it for drainage, and nothing further done.

CLINICAL DIAGNOSES

Acute pancreatitis.
Auricular fibrillation.

DR. MCKITTRICK'S DIAGNOSES

Cholelithiasis, with acute cholecystitis and pericystic abscess.
Choledocholithiasis.
Cholangitis.
Acute hepatitis, with hepatic failure.

ANATOMICAL DIAGNOSES

Choledocholithiasis.
Acute cholangitis.
Multiple abscesses of the liver.
Pulmonary edema.
Icterus.
Operative wound: drainage of liver abscess

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: At autopsy it was still impossible to identify the gall bladder. There was a large abscess in and beneath the liver in the region of the falciform ligament, and the drain had been placed in this abscess. There was a stone in the common duct that completely obstructed it. Above the stone the biliary system was markedly dilated; below, the duct was narrow, and in fact there appeared to be a definite stricture extending from the stone down 25 cm. to the ampulla. The liver was enlarged, and on section was found to contain many abscesses filled with deeply green-stained purulent material. Many of these abscesses could be traced to definite contiguity with the dilated biliary radicles. Cultures showed hemolytic streptococci. This extensive intrahepatic cholangitis was probably the chief cause of death. There was a story of rheumatic heart disease in childhood, and although the mitral valve itself seemed negative, we found some calcification of the annulus fibrosus of the ring — a somewhat unusual lesion, though not an extremely rare one.

The lungs showed atelectasis and extensive edema, but almost no pneumonia.

A PHYSICIAN: What about the kidneys?

DR. MALLORY: The autopsy was done rather long post mortem and showed something that we frequently see in heavily jaundiced patients, occasionally in some other conditions: a sort of lysis of connective tissue throughout the body. The liver cells in such cases fall into jumbled masses, owing to disappearance of the reticulum. The same thing was apparent in the kidneys and the voluntary muscles. The sections are worthless to look at. One cannot possibly say whether or not she had nephritis.

CASE 27072

PRESENTATION OF CASE

A fifty-five-year-old housewife entered the hospital complaining of vaginal bleeding.

The patient's menstrual periods had always been regular until six years before admission, when they increased to twice a month and she noticed the occurrence of frequent hot flashes.

After a year their character changed to small hemorrhages of bright-red blood lasting a week or longer, with staining for four or five days thereafter. Three years before entry the patient suffered a profuse hemorrhage, which lasted a week. She was admitted to another hospital, where an unstated operation was performed, which included, however, an appendectomy, right herniorrhaphy and hemorrhoidectomy. After this procedure, occasional gushes occurred, with staining for four or five days once a month. One year before admission the vaginal bleeding again became profuse, and during the last two months before entry, staining was noticed every day. The hot flashes had disappeared, but she complained of easy fatigability and exertional dyspnea, with occasional dizzy spells when walking. The patient had had two children and one miscarriage.

She had had the usual childhood diseases. The family history was noncontributory.

On examination the patient was very obese and did not appear ill. Examination of the heart and lungs was negative; the blood pressure was 160 systolic, 80 diastolic. Examination of the abdomen showed old surgical scars in the midline and in the right lower quadrant. On palpation it was difficult to feel the uterus, but a large mass believed to be the uterus could be felt bimanually and per rectum. The cervix was slightly eroded, but otherwise negative.

The temperature, pulse and respirations were normal.

Examination of the urine showed a ++ test for albumin, with 40 white blood cells per high-power field, and many bacteria. Examination of the blood showed a red-cell count of 4,100,000. A blood Hinton test was negative.

An operation was performed on the second hospital day.

DIFFERENTIAL DIAGNOSIS

DR. MARSHALL K. BARTLETT: Of course, we should like to know what was found in the abdomen three years before admission, when the previous operation was performed. I think we must assume that if any significant lesion had been found in the pelvic organs and any of them had been removed, we should have been informed about it.

In a woman of fifty-five with vaginal bleeding the first decision to be made is whether the bleeding is due to cancer. There is nothing in the record on which I can make that decision. We can be reasonably certain that the bleeding was not from a malignant lesion in the cervix on the basis of the pelvic examination. Did she have carci-

noma of the endometrium? I do not believe it would give a tumor that would be described, as this is, as a large mass. As you all know, the uterus becomes somewhat enlarged, but it would not be described as a large tumor, unless there was extension into the surrounding structure. Then a large mass might be present, but I think that would be recognized by fixation and so forth. Is this a tumor of the ovary, or is it a fibroid tumor of the uterus? I do not see that we can tell. It is frequently impossible to decide, even when one can examine the patient personally, and I can only accept their statement that it was thought to be uterus, although I see no way of ruling out ovarian tumor. I shall assume that the tumor was in the uterus. In that case the most likely thing would be a fibroid or multiple fibroids, which could account for the bleeding, but it would not necessarily rule out carcinoma of the endometrium in addition. In a considerable number of cases, endometrial carcinoma is found in uteri that contain fibroids. The best conclusion I can come to is that the patient had fibroids of the uterus; there is the possibility that she had carcinoma of the endometrium in addition.

DR. TRACY B. MALLORY: What would your procedure be?

DR. BARTLETT: A diagnostic curettage, a frozen section and a laparotomy should be performed.

DR. MALLORY: Are there any other suggestions?

DR. JOE V. MEIGS: What do the hot flashes mean?

DR. BARTLETT: I suppose she had begun to have the menopause.

DR. MEIGS: They came and went. It makes one think of some ovarian dysfunction.

DR. BARTLETT: Yes.

DR. MEIGS: The intermittent hot flashes bring up the question of an endocrine disturbance such as a physiologic cyst. In a person who has any sort of functional cyst or tumor of the ovary you may see just such a thing. When the estrin is high enough, the patients lose their flashes, and when it is not, they have them. It is a possibility.

DR. BARTLETT: It is a possibility; I had not thought of it. If that were so the endometrium would give a picture to confirm the diagnosis.

DR. MEIGS: At fifty-five she might have a granulosa-cell tumor, with active endometrium but probably no hot flashes. The hot flashes disappear with the development of this particular tumor.

DR. BENJAMIN CASTLEMAN: How about the staining every day? What does that mean?

DR. MEIGS: It might mean a polyp in the endometrium. She might have had either carcinoma or functional bleeding.

CLINICAL DIAGNOSIS

Adenocarcinoma of the uterus

DR. BARTLETT'S DIAGNOSES

Fibroids of the uterus.

Endometrial carcinoma?

ANATOMICAL DIAGNOSIS

Polypoid adenocarcinoma of the uterus, Grade I

PATHOLOGICAL DISCUSSION

DR. MALLORY: A curettage was done on this patient and very abundant material obtained that looked grossly very much like carcinoma. The frozen section was not particularly helpful; the material was composed of such well-differentiated glands that it was difficult to decide whether it was a polypoid carcinoma or simply an atypical polyp. The outstanding feature, however, was the fact that there was no stroma,—each gland backed up against the next gland without any intervening stroma,—and on that ground a diagnosis of cancer was considered justified. A hysterectomy was done. The ovaries, as well as the tubes, were small and atrophic on both sides. The uterus was considerably enlarged—about twice the normal size, I should say. The entire fundus was filled with a papillary tumor that showed very

slight invasion of the myometrium. How long the tumor may have been present, there is no way of guessing.

DR. MEIGS: Do you think that a polypoid type of hyperplasia does become malignant? Novak* states that there is often hyperplasia with adenocarcinoma

DR. CASTLEMAN. We have had two or three cases with hyperplasia and carcinoma in different parts of the same uterus, and this would fit in with Novak's idea.

DR. MALLORY: I cannot remember a case showing simple hyperplasia on curettage that came back two or three years later with carcinoma.

DR. MEIGS: This particular case suggests that there might have been such a development starting six years before.

DR. FRANKLIN G. BILCH, JR.: What are your ideas at the present time, knowing that this was carcinoma, in regard to immediate surgery versus x-ray treatment?

DR. MEIGS: If you have a perfect radium setup, use it, and then operate. By a perfect setup I mean the proper way to apply it; we have it nowhere around Boston except at the Pondville Hospital.

INFLUENZA

DURING the great pandemic of 1918-1919, the number of deaths from influenza throughout the entire world was greater than the total number of persons killed in the five years of World War I. It is not surprising, therefore, that, because of the many similar situations existing today, physicians and laymen alike are following with a great deal of interest reports of increases in the incidence of influenza in various parts of this country. They are all greatly concerned with the possibility that the reported outbreaks represent the preliminary phases of another pandemic.

Just what has been learned during and since the last pandemic that may be of help in preventing or controlling the ravages of another that may

be forthcoming? Briefly, much information was acquired during the 1918-1919 pandemic concerning the clinical, pathological and epidemiologic features of the disease, and a great amount of data was accumulated, which, though not conclusive, has shed considerable light on its etiology. The results of many studies made during the last few years have clarified the etiologic aspects still further. New tools have become available for the study of influenza and similar diseases, and the prospects for better prevention and control are considerably brighter today than they were a decade ago.

The first of the important recent contributions emanated from the Rockefeller Institute at Princeton and concerned swine influenza, the so-called "hog flu" of the veterinarians. Shope¹ showed quite conclusively that this disease is caused by a combination of a filterable virus and a visible bacterium, the latter having the biologic characteristics of *Haemophilus influenzae*, that is, the influenza bacillus of Pfeiffer, but differing from it in immunologic reactions and pathogenicity. In hogs, the filterable agent, that is, the swine influenza virus alone, produces only a relatively mild upper respiratory infection similar in most respects to uncomplicated human influenza; the visible organism, *H. influenzae suis*, by itself produces no demonstrable disease; but the combination of the virus and the bacillus produces a severe type of influenza, with a pneumonia similar to that observed in man during the great pandemic and with a correspondingly high fatality. The similarity of Shope's findings with what is known of the bacteriology and epidemiology of human pandemic influenza, added to the fact that the disease in swine was first recognized during the 1918-1919 epidemic and has recurred almost annually since then, lends support to his theory that the swine disease took its origin from man at that time. These findings also suggest that the severe and highly fatal form of human influenza may be of complex etiology and may involve both filterable viruses and visible agents. In man, the earlier experiences suggested that more than one visible agent may be involved and that, although the Pfeiffer bacillus may play a role in many cases

and in some epidemics, streptococci, staphylococci and pneumococci play the important secondary role in others.

With respect to the disease in man, a great advance was made when Smith, Andrewes and Laidlaw² succeeded in transmitting an infection to ferrets from typical cases of epidemic influenza. This was accomplished by intranasal instillation of filtrates from throat washings. The disease in the ferret differs from that of swine in that visible bacteria take no part in the infection. The hog virus, however, exhibits the same characteristics in the ferret. The filterable virus discovered by these workers, or viruses having the same pathogenicity and similar immunologic characteristics, have now been isolated from many epidemics in this country and in widely scattered places throughout the world. Numerous workers have already added considerably to our knowledge of the biology of the virus and the epidemiology of the infection with which it is associated. The virus can now be transmitted to mice, and it can be grown in tissue cultures and in the tissues of the developing chick embryo. The earlier studies with the influenza virus have suggested that separate serologic races of influenza virus may exist, and this has been borne out by more recent studies. These types of strains from human cases have been labeled "influenza A virus," "influenza B virus" and so forth, and the infections from which they are obtained are called influenza A, influenza B and so forth, respectively.

Animals infected experimentally with these viruses, and persons having clinical influenza during epidemics in which such viruses were recovered develop neutralizing and protective antibodies in their blood, or have an increase in titer of pre-existing antibodies. The experimental animals also develop resistance to reinfection. The duration of the immunity is relatively short, lasting from a few weeks to several months. The antiviral antibodies do not develop or increase in persons who have other respiratory infections, such as common colds, bronchitis and pneumonia.

A number of vaccination experiments have been

made in animals, and some of the results have been of sufficient interest to warrant a limited trial under carefully controlled conditions in human beings. Such investigations are now being conducted purely as experiments, but the results are being awaited with considerable interest. There are no satisfactory data concerning therapeutic experiments with immune serums produced by inoculation of animals with virus, and animal studies with such serums have not been too encouraging. Convalescent serums from human cases were used during the 1918-1919 epidemic in the treatment of a limited number of cases, with variable and mostly equivocal results. It is possible that the use of larger doses given earlier in the disease may prove more efficacious. The sulfonamides are entirely without effect on the virus. It is to be expected, however, that these drugs may favorably affect the secondary pulmonary infections when hemolytic streptococci, pneumococci or staphylococci are involved. There is also the possibility that the pathogenic bacteria cultured from cases of typical influenzal pneumonia are of only minor significance. This is suggested by the fact that in the ferret and in the mouse, the chief pathologic features may be reproduced by virus alone provided that the dose and virulence are adequate. In that event, chemotherapy would have little to offer. The effects on *H. influenzae* cannot be reliably predicted from available data, but will probably not be extraordinary.

Most physicians who had extensive experience with influenza during the 1918-1919 pandemic will probably say that the disease as seen then was radically different from that which has occurred in sporadic outbreaks during the last few years and which they are now seeing. Any deductions based on studies carried out recently must, therefore, be made with the reservation that the pandemic disease may be different in many respects from that occurring during smaller and milder epidemics that are included under the same clinical diagnosis of influenza.

NATIONAL CANCER RESEARCH

THE grants-in-aid, totaling \$271,277.50, that the National Advisory Council has awarded to various institutions and persons constitute a significant contribution to the eradication of cancer; this council was set up by congressional action to advise the Surgeon General of the United States Public Health Service on all matters concerning the federal government's program for cancer research, and the funds, the distribution of which it supervises, are made available by congressional appropriation.

Grants amounting to \$129,085 for fundamental cancer research went to Harvard University; the University of Cincinnati; the Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine; Duke University; the University of Chicago; Dr. B. R. Nebel, of the Experimental Station of New York; Institute of Cancer Research, Columbia University; Dr. John J. Bittner; Cornell University; the Barnard Free Skin and Cancer Hospital, St. Louis; the Michael Reese Hospital, Chicago; the Memorial Hospital, New York City; and Louisiana State University.

An additional \$92,570 was granted to the University of California, the University of Michigan and Washington University of St. Louis for experimental work on the cyclotron, the so-called "atom-smashing" machine, which produces radioactive particles that may prove to be valuable in treating cancer.

The National Research Council (for the American Registry of Pathology), the American College of Surgeons, the New York Hospital, the University of California, Meharry Medical College, of Nashville, Tennessee, and Dr. Harrison S. Martland received a total of \$49,652 for clinical cancer research.

The projected studies of radioactive substances to be produced by the cyclotron now being built by the Carnegie Institution, of Washington, D. C., represent further progress in cancer research; these experiments will be carried out through the collaboration of the Carnegie Institution and the National Cancer Institute. The latter has a staff

of thirty-eight scientists, fifty technicians carefully trained for specific investigations and a laboratory that is the largest of its kind in the world and is also complete with modern equipment.

The help that the Government is extending for research and treatment represents a praiseworthy contribution to the fight against cancer; the experiments stimulated by the grants-in-aid are a step in the direction of control and possibly eventual eradication of the disease.

OBITUARY

ERNEST AMORY CODMAN

1869-1940

Ernest Amory Codman, surgeon, good Bostonian and crusader, was born on December 30, 1869, and died on November 23, 1940, the victim of a painful, prolonged disease following many years of poor health, which he had borne with fortitude. A crusader is one who makes a difficult, dangerous campaign to save something precious, and without thought of gain for himself. Amory Codman's crusade was to ensure for all in need of surgery what he believed to be ideal treatment. Being an independent thinker of vigorous mind, whose emotions were easily stirred, he employed unconventional methods to accomplish his purpose. Perhaps he inherited this tendency from his militant grandfather, the Reverend John Codman. When this Congregational minister became aware that his flock was likely to be contaminated by the teachings of his brother preachers, he refused to allow any other than his own discourses in his church in Dorchester. A hostile element placed another minister in the pulpit and protected him there by a guard. But John Codman climbed up the steps as high as he could, addressed the congregation and walked out with a large majority of those in the church. The opposition soon gave in.

One would not have expected, perhaps, so striking a professional career from this particular Codman's beginnings. He attended a well-known boarding school, enjoyed the usual sports and made good friends among a variety of individuals. An excellent scholar, he ranked high in both school and college. Very early in his boyhood he took to hunting and fishing, sports which he pursued vigorously all his life, for which he always kept himself prepared, and which enabled him, in fact, to withdraw from and forget at intervals his excite-

ing professional life. Few have made better use of an avocation.

As a house pupil at the Massachusetts General Hospital in 1894-1895, he began to do original things. He kept the first ether charts with the idea of showing how harmless a good anesthesia could be. During his years in the Harvard Medical School, he had visited Vienna, where he learned of the importance of disease of the subdeltoid bursa and so secured his introduction to the shoulder joint. This became the love of his professional life, from which he was sometimes diverted but to which he always returned, the subject, finally, of his remarkable book.

When the roentgen ray was discovered in 1895, Codman was one of the first to explore its possibilities, and with his characteristic thoroughness he secured from physicists at Harvard and Technology the best advice and assistance available. It is even more characteristic that, having made complete roentgenologic studies of the important joints of the body, at considerable expense in time and money, all without being asked to do so by anyone, he should have presented his collection to the Warren Museum, where it was buried. Many years later, he came upon his atlas, dusty and apparently forgotten, an event which strengthened the conviction which earlier experiences had created, namely, that his labors were not likely to be recognized. As will presently appear, this attitude of mind, a sense of isolation, a feeling that others would not readily agree with his views, was a strong influence in his life, a peculiarity which in its most violent form caused him to introduce his astonishing cartoon dealing with hospital efficiency and in its mildest form led him to remark to one of his companions in partridge hunting that his dogs were always, like himself, a little queer. It is typical of his own appreciation of this quality that at one moment he should have consulted two alienist friends to inquire whether or not, in his battle for hospital efficiency, he seemed to them the victim of a dominant idea. But his self-consciousness about this matter was never morbid; he was not so introspective as all that. Indeed, he was often more than a little amused at himself.

The turning point in Codman's career came when he was about forty. He had gone up the ladder at the Massachusetts General Hospital and had become an assistant visiting surgeon, associated particularly with Dr. F. B. Harrington. He had begun to write timely, original papers, calling attention, first, to perforated duodenal ulcer and then to its chronic obstructing form. At about this period also, having put the subacromial bursa

on the map, his interest in bones and joints, the fruit of his work in the roentgenologic field, had caused him, with Dr. Henry M. Chase, to write an authoritative paper dealing with the hitherto unexplored subject of injuries to the bones of the wrist, under the title, "Fracture of the Carpal Scaphoid and Dislocation of the Semilunar Bone." He had also repaired with success the ruptured supraspinatus tendon. He was making a good living along rather conventional lines. At this time his conviction "that every hospital should follow *every* patient it treats long enough to determine whether or not the treatment has been successful, and then to inquire, If not, why not?" became the great interest of his life. The products and by-products of his efforts to convince others of the value of this scientific and entirely reasonable idea were truly extraordinary. They included a share in the creation of the American College of Surgeons, and especially its widely accepted standardization of hospitals. They included the Registry of Bone Sarcoma, the enthusiastic services of his hospital staff in the Halifax disaster, the remarkable meeting of the Suffolk District Medical Society and, finally, his book on the shoulder.

A visit to England in 1910 by the Society of Clinical Surgery seems to have been the occasion of the actual creation of the American College of Surgeons. Very likely the idea had been in the minds of many, but Codman tells how he and Dr. Edward Martin, of Philadelphia, discussed the end-result idea in a hansom cab, how hospitals might thereby be improved and how Martin held that "the tail is more important than the dog, but we shall have to have a dog to wag the tail." In 1912, when Martin was made president of the first formal Clinical Congress of Surgeons of North America (the initial step in the creation of the American College of Surgeons) he appointed Codman chairman of the Committee on Hospital Standardization, out of which came in the following year Codman's address to a great gathering on "The Product of a Hospital," in which he preached the revolutionary doctrine that institutions were responsible for the work of their staffs. He called on hospitals to study the product of each surgeon, analyze his results, compare them with those of others and actually enable the public to choose the appropriate surgeon for each disease.

Several years earlier, his desire to demonstrate how a hospital should be conducted had caused Codman to establish one of his own. He took the opportunity, offered by the publication of a series of annual reports, to discuss his success

or failure in each patient treated, explaining the bad results as due to errors of skill, judgment, care and so on. It must be supposed that this excessive frankness and his insistence on an assay by each hospital of the contributions of its staff helped to create, locally, in the profession an atmosphere rather hostile or at least resistant to his ideas. His resignation from the Massachusetts General Hospital in protest against promotion by seniority rather than merit did nothing to dispel this atmosphere, and when he asked to be reappointed and made surgeon-in-chief, on the ground that a study of his results over a ten-year period showed them to be better than those of others, he gave an impression of egotism which hurt his cause. Actually, this seeming boastfulness arose from his desire to be entirely consistent, or if you like, from his "New England" conscience. The record, he held, should govern. His own was open to inspection. Moreover, he believed that in a position of authority he could best carry on the end-result system.

The climax of his campaign was the meeting at the Boston Medical Library. As chairman of the surgical section of the Suffolk District Medical Society, he had arranged a comprehensive discussion of hospital efficiency. His difficulty in securing the speakers on, whom he had at first counted may have caused him to spring his surprise poster on the gathering. Perhaps he had had it in mind all along. In any event, he was a good enough showman to use the mayor of Boston as one of his speakers and to assemble a large and interested audience. Finally he presented his cartoon and explained its meaning. For the benefit of those not familiar with the episode, it should be explained that the cartoon, drawn by his friend, the artist, Philip L. Hale, centers about an ostrich. The bird represents the public. Its head is buried in the sand. It is laying golden eggs, which it kicks into the hands of the faculty of the Harvard Medical School and the staff of the Massachusetts General Hospital. Observations and queries are put into many mouths, and among the figures are several whose faces were true to life. Naturally there was a storm of protest, and Codman was, as he afterward said, in disgrace.

In the very revealing preface of his book on the shoulder,—he calls the book a balloon, of which the preface and epilogue are the basket,—he admits that he may have chosen his path badly, that he should have been either a leader or a satirist, not both. However, being at the same time a realist with a good backbone, he never regretted his escapade. Much of his purpose was accomplished. Special assignments of

surgical subjects had already been given to particular men at the Massachusetts General Hospital, and more specialization followed. An end-result system was created not only at that hospital but over the whole country, an epoch-making achievement: all patients must be followed, for years if necessary; everyone must explain his bad results. The matter was carried far, though not so far as Codman wished. There was no formal ranking of the hospital staff, an impossible feature, as he should have known. Yet one can discern in many institutions a process of sorting out without publicity or formality. There has been a tendency to push particular surgeons into certain fields and to bar them from others. For his too-impulsive action at the library meeting Codman had to pay in loss of dignity, prestige and professional income—a small price, he believed, considering the great result.

Then came the war, the generous volunteering of his hospital staff—with end-result cards to test its efficiency—in the Halifax explosion (1917) and in the following year his unselfish military experience. Serving in this country, he had little opportunity to practice surgery, but found ample scope for his do-or-die spirit in fighting the tragic epidemics which had broken out. As always, he brought along, and made excellent use of, his end-result cards and, of course, his shotgun and fishing tackle.

He returned to civil life in debt, to find his hospital closed and himself somewhat disillusioned about his capacity to alter human nature. He tells that, after having patched up so many splendid young men, he had lost much of his enthusiasm for keeping the aged and infirm alive, and was so filled with a desire to make a little money that he gave up his hospital, which had always been a drain on him, and charged his patients much more than before. Yet when he failed to save one of them—the wife of an intimate friend—he became inspired to make his great fight against bone sarcoma, for which he received no earthly reward.

The Registry of Bone Sarcoma, started in 1920, and his book on the shoulder, published in 1934, though seemingly unrelated to each other and to his end-result idea, were equally a part of it. To begin with, he labored, through the *Boston Medical and Surgical Journal*, as it was then called, to find out if any physicians in Massachusetts knew of any cases of bone sarcoma, particularly of any cured cases. When he discovered, or seemed to discover, that no one read his appeal in the *Journal* or would take the trouble, if they had really done so, to respond, he sent out return

postal cards by the cartoon. On the subject of the shoulder and especially the disabling rupture of the supraspinatus tendon, which he correctly ad- vertised to be an injury of great economic im- portance, he was even more disturbed that he could not secure recognition of his views or im- pose on the profession the need of prompt and successful diagnostic methods. Finally, he de- cided to write the best book on the subject, dedicat- ing it to the end result idea, through the American College of Surgeons. The main portion of the book, the balloon, is of course a masterful mono- graph on the shoulder, the preface and epilogue, the basket, as has already been told, are an arrest- ing and revealing story of his character and life.

To understand Codman one must read the beginning and end of his book. If one thinks of him as in any sense a disappointed man, one will soon find that such was by no means true. He agrees that he has had a good time in life. He calls himself quixotic, but he intensely dislikes being dubbed a "reformer." He certainly describes himself as, though he does not use the word, a "crusader." His creed was to think of the fu- ture, to work for coming generations. If he seemed at times to violate good taste or even professional ethics, he did so with the idea of attacking sham and smugness, the horrors of his life. He never said hard things of those who disagreed with him, only of those whose motives he felt to be un- worthy. And even then, he never attacked indi- viduals. If he liked, he could hold his tongue. He may, in the outbursts of his crusading spirit, have seemed to be a child, but if so, he was an *enfant terrible*, never cried and never asked for another chance.

As a surgeon, Codman did not hold himself to be especially skillful, though he knew himself to be ingenious and resourceful. He was cut out to be, what indeed he was, a "forlorn hope artist." He would see the possibility, which others might have overlooked, of succeeding in a des- perate operation. In overcoming obstacles to this end, he might irritate and annoy a hospital staff, but at last he would accomplish his purpose and secure the approbation of everyone concerned. It was impossible to resist his fundamental goodness and charm.

Amory Codman had many devoted friends in many walks of life. No one could associate with him intimately without coming under the spell of his enthusiasm, his squariness and the attractive whimsical streak which, in all but his most stren- uous moments, took the sharp edge off his intensity. In everyday life he was affectionate, thoughtful, fair, a good companion. His was a strong char- acter, remarkably free from pretense and affecta-

tion, uncompromising, of a sort much needed in this day. He should be counted one of New England's great figures, a man who has left a deep mark and has deserved well of posterity, for whom he labored.

J H

MEDICAL EPONYM

GORDON'S SIGN

Alfred Gordon (b 1869), of Philadelphia, in- structor in nervous and mental diseases, Jefferson Medical College, wrote of 'A New Reflex Para- doxic flexor reflex, Its Diagnostic Value' in *Ameri- can Medicine* (8:971, 1904)

It has been my good fortune to observe a new reflex which I found present in cases, the history of which points to organic diseases of the nervous system, and especially of its motor tracts, I found it always asso- ciated with exaggerated knee jerks, in some cases the Babinski reflex was present, in some not.

The reflex can be elicited in the following manner

The patient may either lie on his back or sit on a chair with the feet (not the legs) on a stool. The feet must be slightly rotated externally, in this po- sition complete relaxation of the muscles of the leg is obtained. The examiner must always place him- self to the outer side of the leg, the thenar and hypo- thenar muscles of his right hand must be placed on the inner surface of the tibia of the patient and the fingers press deeply upon the middle or the lower portion of the calf muscles. I say deeply because the pressure must be transmitted to the flexor mus- cles of the deep layer, sometimes pressure must be combined with lateral movements of the superficial muscles. If the reflex is present, extension of the great toe, or of all the toes, will be noticed. There is evidently no other muscle except the flexors that could be brought into display.

If excitation of the flexors produces an extension of the toes the reflex is certainly paradoxical.

SECTION OF OBSTETRICS AND GYNECOLOGY*

RAYMOND S. TITUS, M.D., *Secretary*
330 Dartmouth Street
Boston

PREGNANCY COMPLICATED BY MITRAL STENOSIS AND PNEUMONIA, AND RESULTING IN CESAREAN SECTION

Mrs F W, a twenty five year-old primipara, was first seen on September 3, 1913, when she was approximately seven weeks pregnant.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

The family history was unimportant. The patient stated that she had had rheumatic fever and St. Vitus's dance as a child. There was no history of any other illness. Catamenia began at twelve, were regular with a twenty-eight-day cycle and lasted five days. The last period began on July 12, making the expected date of confinement April 19, 1914.

Physical examination revealed a well-developed and well-nourished woman. The lungs were clear and resonant; there were no rales. The heart showed no enlargement. There was a question of presystolic thrill, and a murmur that was double at the apex. The apex beat was forcible. The pulse rate was 80. The abdomen was normal. Vaginal examination revealed the uterus anterior and slightly enlarged.

The pregnancy progressed satisfactorily until February 27, when the patient reported that a cold, which she had had for several days, had become much worse. She was unable to breathe and had a bad cough. She also stated that she was having abdominal cramps. She was thirty-two weeks pregnant at that time.

On February 28, the temperature was 100°F., the pulse 110 to 120, the respirations 35, and the systolic blood pressure 95. She was seen in consultation, and a diagnosis of pneumonia at the left base was made.

On March 1 the patient's condition was improved. The temperature was 99°F., the pulse 92, and the respirations 25.

The patient grew steadily better, and when seen on March 24, was completely recovered. The blood pressure at that time was 100 systolic, and the pulse was 80. The lungs were clear and resonant; there were no rales. Examination of the heart was as before. There was slight edema of the ankles. The uterus was enlarged to a size consistent with her dates. The vertex was presenting, but was not engaged. The question of cesarean section arose.

The patient was seen weekly from March 24 until she started in labor on April 19. After a consultation because the head was still not engaged, cesarean section was deemed advisable, and the patient was delivered of a female child weighing 7½ pounds, the only complicating factor being that she lost more than the normal amount of blood. The convalescence was uneventful.

Comment. This case of mitral stenosis resulted from an attack of rheumatic fever and St. Vitus's dance. Today such cases should be seen at the beginning of the pregnancy by competent cardiologists to determine whether the pregnancy should continue, and to supervise the patient properly from the standpoint of the heart condition through-

out the pregnancy. A cesarean section was done because the head was not engaged, and because most cases of mitral stenosis at that time were delivered in this way irrespective of the engagement or nonengagement of the presenting part.

The fact that this patient went through an attack of pneumonia when she was about seven months pregnant without signs of cardiac failure shows that the heart disease was well compensated. In spite of this it would have been much better if she had been confined to bed during the last six to eight weeks.

Subsequently, the patient again became pregnant and was aborted.

MEDICAL POSTGRADUATE EXTENSION COURSES

The following sessions, given by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, have been arranged for the week beginning February 16:

MIDDLESEX EAST

Tuesday, February 18, at 4:15 p.m., at the Melrose Hospital, Melrose. Obstetric Infections: Diagnosis and treatment. Instructor: A. Gordon Gauld. Walter H. Flanders, *Chairman*.

MIDDLESEX SOUTH

Tuesday, February 18, at 4:00 p.m., at the Cambridge Hospital, Mt. Auburn Street, Cambridge. Acute Abdominal Pain: Its interpretation and management. Instructor: Richard B. Cattell. Dudley Merrill, *Chairman*.

NORFOLK

Thursday, February 20, at 8:30 p.m., at the Norwood Hospital, Norwood. Chemotherapy in the Treatment of Gonococcal Infection. Instructor: P. N. Papas. Hugo B. C. Riemer, *Chairman*.

NORFOLK SOUTH

Monday, February 17, at 8:30 p.m., at the Quincy City Hospital, Quincy. Nutritional Deficiencies and the Uses of Preparations of Vitamins. Instructor: Harold J. Jeghers. David L. Belding, *Chairman*.

SUFFOLK

Thursday, February 20, at 4:30 p.m., in John Ware Hall, Boston Medical Library. Diagnosis, Treatment and Prognosis of Central-Nervous-System Syphilis. Instructor: Francis M. Thurmon. Reginald Fitz, *Chairman*.

DEATHS

RICHARDSON — ANNA G. RICHARDSON, M.D., of Roslindale, died February 1. She was in her eighty-first year. Born in Lowell in 1861, she received her degree from the Woman's Medical College of Pennsylvania in 1891 and joined the staff of the Vincent Memorial Hospital a year later. She served successively as assistant surgeon, head surgeon and chief-of-staff until her retirement in

1929 For twenty years she was medical adviser to the New England Telephone and Telegraph Company

Dr Richardson was a member of the Massachusetts Medical Society and the American Medical Association, and was a fellow of the American College of Surgeons

Two nephews survive her

SANBORN—PERLEY L. SANBORN, M.D., of Marblehead, died February 3 He was in his ninety first year

Born in West Unity, New Hampshire, he attended Dartmouth College and received his degree from the Bellevue Hospital Medical College in 1877 He was a member of the staff of the Mary Alley Hospital in Marblehead and was a member of the Massachusetts Medical Society and the American Medical Association

A son and a granddaughter survive him

CORRESPONDENCE

THE NATIONAL LEPROSARIUM AT CARVILLE, LOUISIANA

To the Editor This note was written by a former associate of mine who is now teaching at Louisiana State University School of Medicine. I have greatly enjoyed reading it and think it will be of interest to the readers of the *Journal*

ELLIOTT C. CUTLER

Peter Bent Brigham Hospital,
Boston

Some time ago I visited the National Leprosarium at Carville, Louisiana, and found it very interesting. The Leprosarium is a Marine Hospital operated by the United States Public Health Service. Dr McCreery, the officer of the day, took me on his rounds and talked very interestingly about leprosy, the hospital and many sidelights.

The State of Louisiana originally established the Leprosarium in 1894, and it continued as a state institution until 1920, when the United States Public Health Service took it over. Prior to 1920, the United States Public Health Service appointed a board under the chairmanship of Dr George W. McCoy to select a site for a national leprosarium. Because of the loss of sensation and heat regulatory function of the skin, patients with leprosy fare better in a subtropical climate, and the board therefore considered sites in Florida, California and Texas, the states other than Louisiana from which most of the cases come. However, each time a location was decided on, the surgeon general was informed of local opposition to the establishment of a leper colony, and another site had to be chosen. The problem was finally solved by taking over the state leprosarium by congressional action.

The leprosarium is located on the east bank of the Mississippi River, about sixty five miles above New Orleans. The attending physicians, who are members of the United States Public Health Service, are assisted by several consultants in special fields who come up from New Orleans. Nurses are in charge of the nursing service, because it has been found to be impossible to hire lay people who will give satisfactory care to the lepers. The orderlies and helpers are patients whose leprosy is arrested or has regressed. They receive wages from the federal government for their services. Many of these orderlies are free to leave the hospital because of their improvement, but often they have no desire to go.

There are no wards, all the patients having private rooms. The original buildings consisted of a group of cottages, but a few years ago a large fireproof central building was constructed. It has a capacity of 65 patients and is called the Infirmary. All patients who re-

quire bed rest because of some systemic reaction or who have ulcerations on both feet are cared for here. A few rooms at the end of one corridor were equipped with heavy metal screen doors that could be locked. This provision has been made for mental patients with leprosy, but no patients of this type were in the hospital at the time of my visit.

All buildings are connected by wide 'pikes' covered overhead and screened on the sides. These passageways are very wide, and beds, wheel chairs and bicycles pass through them without difficulty. At present about 50 patients ride bicycles from one building to another. This form of transportation is a great boon to many patients with one bad (ulcerated) foot, who would otherwise be confined to the Infirmary.

This collection of buildings—the cottages and the Infirmary—is distinct from the other buildings that house the medical staff and their families, and the employees of the institution who do not take care of the patients. But there is very little contact between any part of the colony and the outside. River boats pump oil into tanks just inside the levee, and with this source of fuel, the institution maintains its own heating, refrigeration, power and lighting plants, and is quite independent.

Most of the patients at the colony are from southern climes. Halfbreed Mexicans seem to be more susceptible to the disease than members of the white race. Many other patients are of Spanish or French origin. Some are Chinese, Japanese, Jewish, Italian, and, of course, colored. It is impossible to discern nationality after the disease has advanced to certain stages. Dr McCreery told us about an exhibit of pictures of advanced cases of leprosy in patients of different nationalities. Although racial characteristics were easily noted in the early pictures, they were largely erased in the later ones.

The population of lepers in the entire colony during the last seven years has varied between 365 and 385 patients. About 60 cases are admitted annually, but these are not all new ones, since that figure includes some who have deserted instead of going through the routine of being released and readmitted and therefore may be counted as new patients. The 886 patients admitted up to 1938 came from Louisiana (212), Texas (148), California (168), Florida (65), New York (107) and other states (186). However, of the 349 inmates as of June 10, 1938, 140 were born outside of continental United States. Furthermore, many patients were born in states other than those from which they were admitted. Thus leprosy is a disease of aliens in California, but is a disease of native Americans in Louisiana. It has been estimated that the number of unsegregated cases, known and unknown to local health authorities, equals the number of segregated cases. Since Carville has the only leprosarium in the United States, it is readily seen that leprosy is not a numerically important disease in this country. However, an incidence of 50 cases per 1000 inhabitants has been reported in Africa.

Fewer deaths occur from leprosy than from rabies, the latter claiming about 50 lives annually in the United States. At Carville there are about 12 deaths annually, many of these being due to intercurrent infection. Approximately the same number become arrested cases. Some of the patients desert, but those who remain are cared for until something happens to change their status.

The morale of the leper is poor for the first week or ten days at the colony. There appears to be no euphoria as in tuberculosis. He soon makes friends with his kind, however, and many patients become quite cheerful. They have various indoor games to keep them occupied, and

the radio is a big factor in their entertainment. On the southern part of the grounds is a golf course for the use of those patients who are able to take advantage of it. They are dissuaded from being out in the heat of the day, since the bright, warm sun has a tendency to cause some of the lesions to flare up, and also because the patients tolerate heat poorly.

The privacy of the patients is constantly considered. Those seated in their rooms with their backs to the doors were not disturbed. We passed many rooms, presumably because Dr. McCreery knew that our entrance would be resented. Clinics are held weekly, but no patient is forced to attend them. They are asked once to go, and if they express a desire to be excused from attendance, they are not molested or asked again.

There are three varieties of leprosy, the nodular, the nerve and the mixed. The physical examination is important in the early diagnosis of the disease. Alteration in the degree of pigmentation, loss of hair from the eyebrows and, rarely, from the scalp, and atrophy of the skin are noted. Palpation will often reveal the rubbery induration so characteristic of the nodular form of the disease, and in the nerve type the peripheral nerves may be enlarged in a cylindrical, spindle-shaped or beaded fashion. Anesthesia and analgesia can be detected by the usual methods of testing cutaneous sensitivity.

Photographs are used quite extensively to record the findings. I saw some that showed very clearly the early loss of hair from the brows, and the parchment appearance of the atrophic skin. Other photographs recorded cases of ulnar, peroneal and facial nerve involvement. Another group of pictures represented x-ray studies of the bone lesions. The changes in the bones consist of simple absorption and are seen clearly in the small bones of the hands and feet. When pyogenic infection is superimposed on simple absorption, extensive bone destruction is seen. The portal of entry in these cases is usually an abrasion or laceration sustained inadvertently when the patients, who have lost their sense of pain, bump or scrape their hands or feet or burn themselves. To avoid burns from cigarettes, and to accommodate the flexion contracture of the phalanges of the hand, many lepers use very long cigarette holders.

In the laboratory the bacteriologist showed me some slides of the organism and called my attention to the characteristic palisade arrangement of the bacilli. They are found in large numbers in smears and biopsies in contrast to tubercle bacilli. Scrapings of the lesions yield a high percentage of positive smears, but sections are also taken. Nasal secretions are said to be the commonest source of material to be examined to demonstrate an arrested case, but the positive nasal scrapings are so constantly associated with demonstrable nasal lesions that any suggestion of the latter makes examination of the nasal secretions unnecessary.

The first patient we saw had been an advanced case when he was admitted to the colony many years before. Now all he has is some falling in of the nasal bones, slight atrophy of the skin, and evidences of recent operations on the face. I was shown a picture of this patient taken when he had arrived at Carville several years previously, and it was obvious that the lesions had improved markedly. His was the nodular type that causes the leonine appearance because the rubbery induration does not cross the natural skin folds or lines of cleavage. This patient had taken up hunting, and although he made great claims for his prowess in that sport, I was told that his sight was so poor, because of an iridocyclitis and associated corneal opacities due to ulceration, that he often made a mistake in identifying his game and its location. Some

time ago he aimed his gun at what he thought was fair game but the charge went in the direction of a house outside the hospital grounds. The neighbor retaliated by sending a charge of buckshot at the patient, and some of it lodged in the skin of his face. The last of these had been removed just recently.

The youngest patient on record at Carville was three years old, but the disease has been seen elsewhere in a patient nineteen months old. The disease is very rare before the age of ten, yet children are more susceptible than adults. This seems to be a paradox, but the explanation lies in the long period of incubation. One patient was only nine years old and had been admitted to the leprosarium five years before, soon after the diagnosis had been made. His mother, who was also a leper, was admitted at the same time, but she died several months ago. Recently an aunt of the boy was admitted with very early lesions. This is an example of the familial predisposition to the disease that is seen in many cases. Although the boy is only nine years old at present, he has rather extensive lesions on his face and much swelling of his hands and fingers. This swelling, which may also involve the feet, seems to be a common accompaniment of the lesions and is without a general cause, such as renal damage or cardiac decompensation. I noticed that many of the patients had made openings in their shoes to make room for swollen feet.

A group of four patients in one room were listening to a radio program. I thought that one of them was quite young, but I was told that when the lesions become so advanced it is impossible to estimate accurately the age of a patient. The one in question was about thirty years old.

One patient had rather advanced leprosy, and as often happens in such cases, was beginning to show signs of kidney damage. He had edema of the abdominal wall and scrotum and considerable ascites. He had been given twelve doses of Salyrgan without any improvement. Although these patients show evidence of renal failure, no lesion characteristic of leprosy occurs in the kidney. However, nodular infiltration is found in the liver, making it appear to have been sprinkled with white pepper. This patient wore a tracheotomy tube because of laryngeal involvement. I learned that leprosy attacks the upper air passages, particularly the nose and larynx, but does not involve the lower respiratory tract. In the larynx, nodules form on the vocal cords, and scar-tissue contraction follows the ulceration that occurs. The resulting stenosis may cause slight changes in the voice early in the course of the laryngeal lesion, but later, obstruction occurs and acute changes in the obstructed area often necessitate emergency tracheotomy. On the other hand, the ulceration in the larynx may, by its destruction of tissue, bring about improvement by decreasing the degree of stenosis. This improvement, however, is temporary. The incidence of laryngeal involvement is much greater in leprosy than it is in tuberculosis. Three patients with tracheotomy tubes were seen on ward rounds. At one time fourteen patients were thus equipped, and the laryngeal involvement seemed to be almost epidemic.

Another patient had a septicemia due to the leprosy bacillus, and during this blood-stream invasion, fresh crops of macules came out at irregular intervals and were accompanied by exacerbation of constitutional symptoms. Blood cultures had not been done because of the persistent failure of attempts to cultivate the organism. This patient had a lesion on the radial side of the extensor surface of the left wrist. It was light red, brightest at the edge, and smooth and shining, showing a definite outline. Later the macules and the neighboring normal skin be-

came anesthetic. The center of the macule may become white and atrophic. The color of the lesions varies according to the natural pigmentation of the skin. In deeply pigmented skins the macules may be violaceous or copper colored. The reaction to the blood Wassermann test is positive in many cases of leprosy, and this finding, as associated with skin lesions, has often prompted the diagnosis of syphilis. It is not surprising, therefore, that many cases of leprosy have been found in venereal clinics.

In guarding against contagion, simple cleanliness is all that is ordinarily practiced by the physicians, who wear gowns like those used in ordinary contagious wards. After examining patients and palpating some of the lesions with bare hands, thorough washing of the hands is considered sufficient precaution against the disease. I was told that during the last fifty years at this institution no case of leprosy has been considered attributable to contact between patient and personnel.

The organisms are found in biopsies of lesions of the anesthetic type if taken during the inflammatory stage. It is said, however, that this type of lesion is not responsible for spread of the disease because the organisms are not discharged from them.

Even when the disease is active, patients may be released for sufficient reason but must travel in a private conveyance. Often a patient whose wife may be ill or dying does not wait for an official release. He simply deserts, hops a freight train, and when the urgent matter is taken care of, he reports back to the institution. These patients encounter no difficulty in being readmitted.

Patients may be paroled when the lesions are considered inactive. Two factors are considered in arriving at this conclusion. The lesions must be inactive from every clinical standpoint, and examination of scrapings from the lesions must show no organisms on twelve different occasions. Such patients return from time to time for re-examination, and if the lesions become active again, they must return to the colony.

The only treatment other than excellent general hygiene consists of chaulmoogra oil. A supply of it is kept on the dining tables and is used at each meal. An ethyl ester of chaulmoogra oil has been used intramuscularly, and sodium chaulmoograte has also been given a trial. There is some doubt about the efficacy of these preparations, and it was my impression that little progress has been made in the treatment of leprosy.

I heard about John Early, the famous leper. John Early's home was originally in one of the Carolinas. He was educated in law, in addition to a sound general education, and developed a good command of the English language. He turned from law to religion and became a preacher of a radical type. At some time during his early years he was on military duty in the Philippines, and it is said that this is where he contracted his leprosy.

He was well known throughout the United States Public Health Service because of his many escapes from the colony. His most famous escapades consisted of trips to Washington, where he attempted to impress government officials with the need for changes at the leprosarium, which they had ignored when he attempted to handle matters by correspondence. It is said that he was paid great attention at one time when he registered at a prominent hotel in Washington and later announced that he was John Early, the famous leper.

Following one of his later escapes he made his way to California and acquired a house and a car, and recorded his ownership of them in such a manner that considerable provision had to be made for their disposal before he could be returned to the colony. I believe that a patient

cannot be sent to Carville unless some satisfactory arrangements have been made for the disposal or care of his property.

Back in the hospital again he wrote an autobiography. Whatever the contents of the book, they were censored so much that not more than enough material for a single chapter remained. Undismayed, he tried to have it published under the title of *The Fourteenth Chapter in the Life of John Early, the Famous Leper*. I do not know whether it ever reached book form.

His last escape was made shortly before his death. This time he went back to his native Carolina hills. A doctor and an attendant from Carville were sent after him and, with the aid of several local peace officers, finally found John Early. However, no one would touch him except the two from Louisiana and it remained for them to drag him down the mountainside and back to the leprosarium. On his return, his sight and hearing failed rapidly and he died soon thereafter.

In the pathology laboratory there is a large glass specimen jar on which is a label headed "Treasury Department". In this container rest some of the remains of John Early. The many stories about this patient will probably keep his memory alive for a longer period of time than will the specimens in the jar bearing his name.

This long story has omitted many little incidents that occurred during my short visit, but to one who had seen only three cases of leprosy before, this experience was extremely interesting and instructive.

JOHN L. KEELEY, M.D.

NOTICES

MASSACHUSETTS MEMORIAL HOSPITALS

There will be a staff meeting of the Massachusetts Memorial Hospitals in the Evans Memorial Auditorium on Friday, February 28, at 8 15 p.m. Dr. C. W. Sewall will preside.

PROGRAM

- Hypertension and/or the Albuminuria of Pregnancy
Dr. Foster Kellogg Discussion by Dr. Duncan Reid
- Postnatal Care A year's study in the Follow Up Clinic
Drs. C. W. Sewall and O. C. Mullaney Discussion by Dr. J. T. Williams

NEW ENGLAND PATHOLOGICAL SOCIETY

The next meeting of the New England Pathological Society will be held on Thursday, February 20, at 8 p.m., at the Mallory Institute of Pathology, Boston City Hospital.

PROGRAM

- Eosinophilic Granuloma of Bone Dr. L. S. Jolliffe
- Intranuclear Inclusions in Infants Dr. T. D. Kinney
- Inter-capillary Glomerulosclerosis Drs. H. Jeghers and O. J. Wollenman, Jr.
- The Pathology of Athetosis Is it malformation or birth injury? Dr. L. Alexander

MASSACHUSETTS DEPARTMENT OF CIVIL SERVICE AND REGISTRATION

School Physician, Department of Health, Worcester, \$1200 a Year

Director of State Civil Service, Ulysses J. Lupien has recently announced that a competitive examination is to

be held on April 26 in order to find eligibles for appointment to the position of school physician, Department of Health, Worcester.

The entrance requirements are as follows: applicants who have not reached their thirtieth birthday on the day of examination will not be eligible to apply; applicants must be registered physicians under the State Board of Registration in Medicine. The subjects and weights of the examination are as follows: training and experience, 2; practical questions, 3; total, 5. Applicants must obtain a grade of 70 per cent in each subject in order to become eligible. The last date for filing applications is Saturday, April 12, at 12 o'clock noon.

NEW ENGLAND BRANCH OF THE AMERICAN UROLOGICAL ASSOCIATION

The ninety-first meeting of the New England Branch of the American Urological Association will be held at the Harvard Club of Boston, on Thursday, February 27, at 8:15 p.m.

PROGRAM

Recent Advancements with Chemotherapy in Infections of the Urinary Tract. Dr. E. N. Cook, of Rochester, Minnesota.

Chemotherapy in Gonococcal Infections. Dr. O. F. Cox.

Formal discussion to be opened by Drs. C. S. Keefer and Champ Lyons.

NORFOLK DISTRICT MEDICAL SOCIETY

A regular meeting of the Norfolk District Medical Society will be held at the Hotel Puritan, Boston, on Tuesday, February 25, at 8 p.m. Tel. KEN 1480.

PROGRAM

Business.

Medicolegal Meeting. Mr. Leland Powers and Dr. W. J. Brickley.

Discussion.

Collation.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

There will be a meeting of the New England Society of Physical Medicine at the Hotel Kenmore, Boston, on Wednesday, February 19, at 8:00 p.m. A business meeting at 6:00 p.m. will be followed by an informal dinner in the Empire Room at 6:30 p.m.

PROGRAM

Medical Preparedness. Dr. Walter G. Phippen, president, Massachusetts Medical Society.

All members of the medical profession are cordially invited to attend.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, FEBRUARY 16

SUNDAY, FEBRUARY 16

†4 p.m. The Use and Abuse of Vitamins. Dr. Maurice B. Strauss. Free public lecture. Harvard Medical School, Building D.

†4 p.m. Our Food and Our Health. Mrs. Muriel L. Reese. Cambridge Hospital, Margaret Jewett Hall.

MONDAY, FEBRUARY 17

12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

TUESDAY, FEBRUARY 18

*9-10 a.m. The Psychosomatic Problem: Its significance for the physician. Dr. Kurt Goldstein. Joseph H. Pratt Diagnostic Hospital.

*12 m. Chronic Arthritis. Dr. Frank R. Ober. South End Club. Headquarters of the Boston Tuberculosis Association. Columbus Avenue, Boston.

12:15-1:15 p.m. Clinicoroentgenological conference. Peter Bentham Hospital amphitheater.

WEDNESDAY, FEBRUARY 19

*9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. H. Pratt Diagnostic Hospital.

*12 m. Clinicopathological conference. Children's Hospital.

*2-4 p.m. Anemia. Drs. W. P. Murphy and Robert Zollinger. Bent Brigham Hospital.

8 p.m. Boston Society of Biologists. Massachusetts Institute of Technology.

*8 p.m. Medical Preparedness. Dr. Walter G. Phippen. New England Society of Physical Medicine. Hotel Kenmore, Boston.

THURSDAY, FEBRUARY 20

*8:30 a.m. Combined clinic of the medical, surgical, orthopedic, pediatric services of the Children's Hospital and the Peter Brigham Hospital, at the Children's Hospital.

*9-10 a.m. The Perennial Tonsil Problem. Dr. W. A. MacColl. J. H. Pratt Diagnostic Hospital.

8 p.m. New England Pathological Society. Boston City Hospital Mallory Institute of Pathology.

FRIDAY, FEBRUARY 21

*9-10 a.m. Some Characteristics of Experimental Deficiency Diseases. Dr. O. A. Bessey. Joseph H. Pratt Diagnostic Hospital.

*Open to the medical profession.

†Open to the public.

BOOK REVIEWS

New Facts on Mental Disorders Study of 89,190 cases By Neil A Dayton, MD, MC 8°, cloth, 486 pp., with 110 graphs and 84 tables Springfield, Illinois Charles C Thomas, 1940 \$4.50

This book is a statistical study of the patients admitted to Massachusetts state mental hospitals during the years 1917 to 1933 inclusive. The collection of data on which the study is based was initiated by the late Dr. George M. Kline, commissioner of the Massachusetts Department of Mental Diseases, who secured a grant from the state legislature in 1926 for the purpose. The study extended over the ensuing period of eight years, with the aid of grants from the Laura E. Spellman Rockefeller Memorial Fund. The laborious task of organizing and analyzing the mass of data thus collected has been carried out since 1935 by Dr. Dayton with the help of an assistant and clerical workers and with the financial aid of the Rockefeller Foundation.

For the purposes of the study, the 89,190 cases that came under consideration were divided into four groups: 56,579 first admissions 'with mental disorder', 9,299 first admissions without mental disorder, 20,635 readmissions with mental disorder, and 2,677 readmissions without mental disorder. After discussing the social and economic developments of the eventful years 1917 to 1933 (World War I, Prohibition, Depression) and considering possible influences on the number of persons admitted to mental hospitals in Massachusetts during those years, the author proceeds to the statistical analysis of the four groups of cases, with reference to age, nativity, alcoholism, marital status and clinical diagnosis. In the last chapter the author answers the question, 'Are mental disorders on the increase?' as follows: 'The larger part of the supposed increase in mental disorders has come about mechanically, through the extremely long hospital stay of patients with this type of illness. Only one sixth of the total increase could be attributed to rising numbers of admissions.'

It is impossible in a brief review to deal adequately with the numerous conclusions that emerge from the welter of data. A few of the highlights may be mentioned. Mental disorder is a disease of old age, and 'The highest proportion of newly developing cases of mental disorder (first admissions) do not occur in the younger or middle ages but in persons who have proved their adequacy by several decades of successful living. The foreign born present the highest admission rates, and the native born of native parentage the lowest. Chronic alcoholism is a prominent etiologic factor in one fifth of all admissions to mental hospitals in Massachusetts, and the evidence suggests that Prohibition may have been more successful especially with women, in controlling alcoholism (even in the depression years) than has generally been realized. This suggestion may, however, be a reflection of decreased facilities for caring for alcoholic patients in the mental hospital system. The author concludes that the married have the least chance of developing mental disorders of any of the marital groups. The widowed, the single and the divorced, in order, show a higher incidence of mental disorders. An interesting detail is an apparent relation between religious denomination and the incidence of mental disorder. Protestants present the highest admission rate and are followed in order by the Catholics, other denominations and the Hebrews. The leading mental disorders in the Protestants are psychoses with Huntington's chorea and the senile psychoses in the Catholics the alcoholic psychoses and psychoses with mental deficiency,

and in the Hebrews the psychoneuroses and undiagnosed psychoses.

There is no doubt that this book is an extremely important and authoritative contribution to general psychiatric literature, it is certainly destined to become a standard reference that will be widely consulted and quoted for many years. Typographic features that deserve special mention are the many excellent graphs and the concise summaries at the beginning of each chapter.

Edinburgh Post Graduate Lectures in Medicine Vol 1 8°, cloth, 513 pp., with 110 figures, 32 tables and 11 charts Edinburgh Oliver and Boyd, 1940 10s 6d (\$2.10)

This volume of lectures delivered at the Royal Infirmary, Edinburgh, Scotland, is part of the postgraduate program organized over a generation ago in this great medical center. It is of timely interest to physicians in New England, where a similar program is now being intensively developed. With us, as in Great Britain, it has become recognized that provision for postgraduate study is necessary if our profession is to maintain that high standard of efficiency upon which we pride ourselves, and that the physician must remain a student throughout his active professional life.

The thirty-three lectures comprising this book come from men who are authorities in their respective subjects, among them Edwin Bromwell, Sir David Wilkie and W. T. Ritchie. The range of subjects is wide and interesting, and particular emphasis is laid on their application to general practice. Several of the topics may be cited: 'Upon the Pupil Reaction,' 'Some Modern Problems in Neurology,' 'Practice, Rational Use of Treatment of Nephritis,' 'The Acute Abdomen in Childhood,' 'The Lungs and Pleura—Certain Anatomical Facts in Relation to Disease,' 'Recent Development in the Surgery of Obstructive Jaundice, with Special Reference to the Risk of Hemorrhage.'

In form and in content this book is worthy of the high Edinburgh tradition. It is labeled Volume One. May it be followed by many more!

Clinical Heart Disease By Samuel A. Levine MD Second edition, revised and reset. 8°, cloth, 495 pp., with 109 illustrations Philadelphia and London W. B. Saunders Company, 1940 \$6.00

The second edition of this already well known book follows in general the form and content of its predecessor. The presentation of the subject lends itself to easy reading and properly reflects the experience of the author as an investigator, a teacher and a specialist in the field of cardiovascular disease. A number of welcome additions and amplifications of practical importance appear in the new edition.

The book is designed and written primarily for the practicing physician. However, the special student of cardiovascular disease will encounter with interest many original ideas that have appeared in special publications in the past by the author and his associates here to be re-emphasized, modified or abandoned in the light of further experience. For example the operation of valvulotomy for mitral stenosis, proposed in 1923, has rightly been discarded as impracticable, the use of adrenalin administered subcutaneously as a test for angina pectoris in questionable cases, as the author points out, is fraught with danger and the routine administration of quinidine sulfate following acute coronary thrombosis as a prophylactic

measure against fatal ventricular fibrillation has been modified in favor of its occasional use in special cases. With these recommendations there is general agreement. It is with mild disappointment, however, that one finds again in the new edition the suggestion that rheumatic infection may be the result of "some inherent hereditary defect in metabolism associated with growth or with the glands of internal secretion that renders some individuals particularly susceptible to some noxious agent that is fairly prevalent." To the reviewer, such speculation seems unduly fanciful. The discussion of angina pectoris and of coronary thrombosis is especially well arranged and should be most helpful in the management of patients with these disorders of the heart. Certain outstanding clinical problems are well emphasized in special chapters; for example, "Acute Cardiovascular Emergencies" and "The Clinical Significance of the Systolic Murmur." Furthermore, the newly added chapter, "Medicolegal Aspects of Heart Disease," will be especially welcome to the physician who, often against his desire, either on the witness stand or elsewhere finds himself faced with difficult decisions in connection with this aspect of heart disease.

The field of clinical electrocardiography is covered adequately, with well-chosen illustrations, in the final chapter of the book. Perhaps the rather gloomy outlook with which the author views the finding of evidence of intraventricular block, especially of the left-branch type, might have been tempered by the brief mention of so-called "functional-bundle-branch block" with a short PR interval—rare, to be sure, but important to be recognized.

The medical profession is fortunate in having available a new and up-to-date edition of this book, which is especially adapted to the needs of the practicing physician. Its continued usefulness is assured.

The Control of Tuberculosis in the United States. By Philip P. Jacobs, Ph.D. Revised edition. 8°, cloth, 387 pp. New York: National Tuberculosis Association, 1940. \$2.00.

This book should prove useful to those interested in tuberculosis as well as to all who seek information concerning methods of preventive medicine.

The author was for many years associated with the educational and publicity program of the National Tuberculosis Association, and wrote extensively on health education. It is therefore fortunate that this work was completed before his untimely death.

The book deals with the history of the antituberculosis movement, and with methods for the control of tuberculosis in the United States. The subject matter is exhaustively treated, dealing with such varied topics as fund raising and case findings. There are excellent chapters entitled "Adult Health Education," "Social Service and Rehabilitation," "The Negro Problem," "Treatment and Hospitalization" and "Relations to the Medical Profession." The fundamental principles of the tuberculosis programs also receive attention.

The book reflects Mr. Jacobs's attitude as a crusader and enthusiastic teacher who understood in a practical way the psychology of health education under a democratic system. The style, although simple, is forceful, and the subject matter concisely but thoroughly treated. This book is the fruition of an active mind and scientific training in a chosen field.

All interested in disease-control programs will find valuable information in this work.

Gynecological and Obstetrical Pathology, with Clinical and Endocrine Relations. By Emil Novak, M.D., D.Sc. (Hon. Dublin). 8°, cloth, 496 pp., with 427 illustrations. Philadelphia: W. B. Saunders Company, 1940. \$7.50.

This is an excellent book, presenting as it does the lesions of the female genital tract from the point of view of a gynecologist. It is easy to read and covers the subject very adequately. In addition there are excellent chapters on the normal physiology of the ovaries and pituitary gland, with their endocrine relations, and on the normal histologic changes in the endometrium in the course of the menstrual cycle. The pathologic states of each organ are grouped together in sections, and preceding each is a short description of the normal.

A major fault of the book is in the illustrations. The title page states proudly that there are four hundred and twenty-seven of them, but of these probably no more than a quarter are above criticism. This is because, in the first place, they were originally low-power photomicrographs, and, in the second, they seem to have been reduced in size in the printing. The result is a picture that lacks sufficient detail to mean much to anybody but an expert. It is also a very personal book, but what axe grinding there is does not intrude too much.

All in all, the average obstetrician and gynecologist should certainly have this book available for reference. Its use is greatly facilitated by a well-arranged twenty-three-page index.

Electrocardiography. By Chauncey C. Maher, M.D. and Paul H. Wosika, M.D. Third edition. 4°, cloth, 334 pp., with 42 diagrams and 5 radiograms. Baltimore: Williams and Wilkins Company, 1940. \$4.00.

Electrocardiography has developed into another useful and important procedure for the clinician. Like the Wassermann test and x-ray examination, the electrocardiogram offers important data to be included or corroborated with the other clinical observations to arrive at an accurate diagnosis. The physician who observes the patient is the final judge in each case, even though the laboratory evidence may voice a dissenting opinion.

With this view in mind, the book is illuminating and practical. It gives the physician-student of medicine an opportunity to acquire a fundamental knowledge of electrocardiography. The one hundred electrocardiograms that are reproduced and discussed cover a goodly number of the common varieties of cardiac disease, including the arrhythmias, conduction deformities, axis deviations and changes that result from coronary occlusion. There are also a number of diagrams illustrating the intrinsic mechanism of the heart beat.

The arrangement of the book is in a convenient form, showing the electrocardiogram on one side of the page and its interpretation on the opposite one, preceded by a clinical diagnosis. The interpretations are clear, precise and conservative. This edition includes the fourth lead, the most notable recent addition to electrocardiography. The book is highly recommended.

Correction

The reviewer of *The Diagnosis and Treatment of Diseases of the Peripheral Arteries*, by Saul S. Samuels, wishes to correct an erroneous impression that may have been obtained from the review published in the issue of December 26, 1940. The opening sentence of the third paragraph of the review should have read, "Some of the subject matter in the book appears to be misleading to the reviewer," inasmuch as in the reviewer's experience Uroselectan is an irritating solution for arteriography.

NUMBER 8

FAVORABLE TYPES OF BRAIN TUMOR AND THE RESULTS OF THEIR OPERATIVE REMOVAL¹

GILBERT HORRAN, MD†

BOSTON

ALTHOUGH it is within comparatively recent years that the natural history and useful survival periods of patients harboring various types of brain tumor have been the subject of investigation, the published reports have been surprisingly few. The vast majority of these have come either from Harvey Cushing himself or from his pupils. In van Wagenen's¹ report in 1934 of 149 cases from Cushing's clinic seen eight years previously, the survival rate for all types of tumor (benign and malignant) was 35 per cent. From a review of this material it appears that 75 patients—roughly half—had what might be called "favorable tumors." Of these, 45, or 60 per cent, as nearly as can be made out, were leading useful lives.

In 1936 Cairns² made a somewhat similar though more exhaustive study of 157 cases seen in Cushing's clinic nine years previously. There were 22 postoperative deaths, leaving 135 patients on whom the study was chiefly based. Sixty-three of these patients were living at the nine-year interval, giving a survival rate for the entire series of 40 per cent. It is difficult to estimate the number of patients out of the original 157 who had favorable tumors, but from the tabulation it is safe to say that 78, or about half, harbored growths of this character. Cairns estimates that 37 patients were leading useful lives at the time of his study, and since these were all among the favorable tumors, 47 per cent, or nearly half, apparently came into this category.

The conclusions that I have drawn from the data given in Cairns's and van Wagenen's papers are at best only rough estimates, but I think that one is justified in saying that at least 50 to 60 per cent of the patients having favorable tumors in these reported series were living useful lives

eight and nine years after operation. That this percentage was not considerably higher I take to be owing to two operative features that show the advances in neurosurgery. First, in the years that both these series of cases were operated on, trans sphenoidal operation for pituitary tumors was being used. The results from this type of operation, although at times brilliant, were on the whole far less complete or permanent than the intracranial operation later used by Dr. Cushing and now almost universally employed by all neurosurgeons. Secondly, the operation for acoustic neuromas was, in those years, the so called "intracapsular extirpation." By this means a shell of tumor with a greater or lesser amount of tumor cells was left behind, and recurrence was inevitable. At the present time these tumors, almost without exception, should be totally removed, with a mortality no greater than that of the incomplete operation, that is, slightly less than 10 per cent.

A much more comprehensive report of survival periods was published by Eisenhardt³ in 1935 from the records of Cushing's complete series. Of about 2000 patients it appears that 499, or almost exactly 25 per cent, had survived from five to twenty-eight years following operation, but if one deducts the immediate operative deaths (approximately 400), the figure for the remainder is 31 per cent. This survey, like those of van Wagenen and Cairns, included all tumors, benign and malignant, but did not deal with the question of useful survival; therefore this feature and its relation to the favorable types of tumor cannot be estimated from the data available.

It is evident from the contents of the articles just quoted that the vast majority of patients surviving five or more years were those who harbored favorable tumors. It has been my purpose, therefore, in the present discussion, to look up the number and percentage of these favorable tumors in my own series, to tell what has been done for them

¹Presented at the annual meeting of the New England Surgical Society, Poland Spring, Maine, September 27, 1940.

†Neurosurgeon, Lahey Clinic.

and to gain as clear an idea as possible of their survival and state of usefulness, since after all it is only useful survival that should be the aim of any form of therapy. Furthermore, it is only by going over one's material, following the patients for many years, and putting the facts on paper, that the profession and the public can be made to realize that there is an entirely hopeful side to the surgery of brain tumors and that a large percentage of patients can be and are completely cured.

The material on which the present study is based consists in the hospital records and follow-up reports (by personal interview or letter) of 400 consecutive patients with brain tumors that were verified pathologically from November, 1932, to June, 1939. Of this total number I have classed 224, or 56 per cent, as favorable tumors. By the term "favorable" as here used is meant tumors that were capable of complete and permanent removal, resulting in cure of the patients. This does

ever, is that in going over the records of all these 400 patients carefully it is apparent that well over 50 per cent harbored tumors that were, or should have been, totally extirpated. Among the 224 favorable tumors there were 27 operative deaths, a mortality of 12 per cent. This leaves 197 survivors, but of these, 10 have died subsequently,

FIGURE 1. *Localized Thinning and Increased Vascularity at the Site of a Meningioma near the Vertex.*

not, of course, imply that all the 224 patients had their tumors removed and were cured. In a few cases the technical or other difficulties apparently prevented complete removal, and there was obviously an inescapable operative mortality, which will be given. What I wish to make clear, how-

FIGURE 2. *Calcification in a Parieto-occipital Meningioma.*

leaving a final figure of 187 patients who are living and whose tumors I believe to have been wholly eradicated.

Coming now to the pathological types of favorable tumors, one finds that the 224 may be classed as follows: meningiomas, 80; acoustic neuromas, 33; pituitary adenomas, 30; gliomas (mostly cystic), 29; miscellaneous, 52. A note of explanation is due the miscellaneous group. Rather than give a long list of comparatively infrequent tumors, it has seemed best for the present purpose to put together in this category the remaining favorable growths, including certain angiomas, hemangiomatous cysts, colloid cysts of the third ventricle, certain craniopharyngiomas and pinealomas, cholesteatomas and unclassified tumors.

A brief word may now be said about the diagnosis of and the operations on these favorable tumors. The meningiomas, as might be expected, head the list. They are the solid encapsulated growths, usually occurring over the cerebral con-

vexities and often arising from or invading one of the major venous sinuses. Sometimes, however, they are found nestling between the optic nerves, or growing to huge size under both frontal lobes. Frequently they give recognizable changes in the skull by x-ray—increased localized vascularity, bony thickening or spiculation, enostoses, calcification or what appears to be a large osteoma overlying an intracranial tumor (Figs. 1 and 2). Although all the tissues surrounding meningiomas

then be removed piecemeal by the electrosurgical loop, and finally the capsule of growth pulled away from the overlying brain and underlying optic nerves.

Acoustic neuromas are the second type of favorable growths. These are the well-recognized cerebellopontile-angle tumors, perfectly benign and completely encapsulated. Almost always they may be diagnosed from the clinical picture: tinnitus and increasing deafness on one side, fol-

FIGURE 3. Extirpation of a Surface Meningioma.

are highly vascular, which makes their removal at times extremely difficult, in almost every case they are capable of complete extirpation if one has a thoroughly trained team of co-workers. At times it is essential to remove many centimeters of the longitudinal or lateral sinuses, and large areas of skull that have been invaded by tumor.

When the meningioma is attached to the dura over one of the cerebral convexities, the dura is incised around the growth, blood vessels between it and the surrounding cortex are ligated either by electrocoagulation or silver clips, and by working around the tumor in this way it can gradually be tilted out from its bed and thus completely extirpated (Fig. 3). The large growths arising from the olfactory groove and extending under both frontal lobes must be attacked in a different way. Usually the anterior part of the right frontal lobe is excised, thus exposing the upper pole of the tumor. The contents of the tumor capsule can

be removed by numbness of the same side of the face, staggering, headaches and in the later stages failing vision due to choked disks. Until recent years the common practice was to do an intracapsular extirpation of these tumors, but with this operation, although the result in some cases was good for several years, the growth always recurred and secondary operations were either unsatisfactory or carried a high mortality. I therefore always remove the tumor completely at the primary operation, and find that the mortality is no higher than that for the incomplete operation, namely, a little under 10 per cent. The one disagreeable feature of complete removal of these tumors is the resulting inevitable facial paralysis. This, however, can be overcome largely by a spinofacial anastomosis (Fig. 4). The operation as now done consists in a unilateral exposure of the affected cerebellar hemisphere, excision of the outer third of the lobe, intracapsular extirpation of the tumor

and, finally, withdrawal of the capsule by careful and painstaking separation from the pons, the trigeminal nerve and the blood vessels in the area (Figs. 5 and 6).

The third group of favorable tumors is that of the pituitary adenomas. They may be diagnosed by the familiar triad—optic-nerve atrophy, partial or complete bitemporal hemianopsia and an enlarged sella turcica, discernible by x-ray study

the hair line. The contents of the tumor capsule are evacuated, after which the capsule is removed down to the clinoid processes (Fig. 8). There is some tendency for pituitary adenomas to recur, but if so they may be reoperated on with little, if any, added risk.

Benign gliomas (usually cystic astrocytomas) are the fourth group of favorable tumors. They may occur in the cerebral hemispheres, but are

FIGURE 4. *Partially Corrected Facial Paralysis by Spino-facial Anastomosis following Complete Extirpation of an Acoustic Tumor.*

(Fig. 7). Much has been written of late years concerning the role of x-ray treatment for these growths. It is true that a certain number of patients, probably under 25 per cent, will get a recession of their visual symptoms, at least for a while, by means of x-ray therapy, and for those whose vision is not already seriously affected I should advocate a trial by radiation. Patients must be followed carefully for a considerable time, since vision may fail insidiously and subsequent x-ray treatment may not be helpful. I have had many unfortunate patients who had tried this form of treatment, were helped for a while and then were not urged to seek further relief until vision was well-nigh gone and their tumors so extensive that they were inoperable. Operations for pituitary adenomas in the stage in which they should be operated on should not carry a mortality of over 5 per cent. The growth is approached by a frontal bone flap from an incision concealed within

commoner in the cerebellum and most frequent in children. The story is often one of intermittent bouts of headache and vomiting. Neurologically, cerebellar signs and symptoms are as a rule outspoken. Whenever found, the cystic portion of the tumor is evacuated, and the solid portion completely extirpated by electrosurgical methods (Fig. 9). After this, it is never necessary to remove the cyst wall or to fix it with hardening or sclerosing solutions.

In the miscellaneous group of tumors, attention should be called to a few of the outstanding points. Hemangiomas of the cerebellum occur in adults and give the usual cerebellar symptomatology, together with pressure signs. Just as in astrocytomatous cysts, the cavity is evacuated and the mural nodule—usually bright-red—is excised. The angiomas are dealt with almost entirely by electrocoagulation and occasionally by subsequent x-ray therapy. Colloid cysts of the

third ventricle are uncommon, but are small tumors about the size of a cherry, situated at the foramen of Monro. They give no localizing signs and are always diagnosed by ventriculography. They are removed after exposure of the foramen by a cortical incision down to the dilated ventricle. The favorable craniopharyngiomas (cysts of Rathke's pouch) are approached and removed by the usual frontal craniotomy employed for pituitary adenomas. Many tumors of this type are

FIGURE 5 Preliminary Excavation of an Acoustic Neuroma after Excision of the Outer Third of the Cerebellar Hemisphere (Horrax and Poppen⁵ reproduced by permission of the publisher)

extremely extensive and adherent to important basilar nerves and arteries and therefore are not included in the favorable list. A few pinealomas are capable of complete extirpation by radical operative exposure, and I have two patients with these tumors who have survived three and seven years respectively. Cholesteatomas (pearly tumors) are rare but almost always favorable.

As stated previously, this study concerns the present status of 224 patients who were considered to have favorable brain tumors out of a total series of 400 verified tumors of all types. Deducting the postoperative and subsequent deaths, there have so far been 187 survivors. Since the operations on these patients dated from November, 1932, to June, 1939, it is obvious that the follow up record varies from slightly over one to nearly eight years. It is fully realized that a greater time interval would have given a much more accurate picture, but the figures here presented are offered for what they are worth.

In going over the follow up data of the 187 survivors, it is obvious that 27 have major disabilities or handicaps that prevent them from living useful

lives.* Among the meningiomas, partial motor paralyses and convulsions are the outstanding features. Patients who have had acoustic tumors show residual ataxia, in a few cases sufficient to keep them from work. Three of the acoustic patients had become blind before they presented themselves for operation, and blindness from such secondary atrophy is almost never capable of any useful return of vision, even though intracranial pressure is entirely reduced. Blindness, however, is even more prevalent among the pituitary adenomas. This means that the tumors had almost certainly been present for many years before the malady was diagnosed, or else, as mentioned previously, x-ray treatment had been continued for too long a time without adequate checking up. But whatever the cause of disability, by far the

FIGURE 6 Extraction of the Remaining Acoustic Tumor Capsule after Separation from the Trigeminal Nerve and Other Neighboring Structures (Horrax and Poppen⁵ reproduced by permission of the publisher)

greater portion of them could have been prevented by an earlier diagnosis and an earlier removal of the tumor.

Going back to the 187 surviving patients, therefore, and deducting the 27 who have severe disabilities, one obtains a final total of 160, or 71 per cent of the original 224 with favorable tumors, who not only have survived but are leading useful lives with little or no functional loss.

605 Commonwealth Avenue

*One patient although completely blind has not been included in this list because he has carried on an important executive job ever since his operation in spite of visual loss.

DISCUSSION

DR. WILLIAM J. MIXTER, Boston: Dr. Horrax has given us a very valuable résumé of his cases of brain tumor. His

is the malignant glioma that has given brain surgery more or less of a bad name.

I believe that one of the advances that will come in the surgery of brain tumor will be our ability to recognize these malignant cases without turning down an osteoplastic flap. Should we be able to achieve this, we shall be in a position to eliminate exploratory operations in many of these unsatisfactory cases.

DR. ELLIOTT C. CUTLER, Boston: I should like to ask Dr. Horrax whether the nodule in the so-called "fibrillary astrocytoma" is the basis for the output of the fluid in the cysts. It is difficult to comprehend how glial cells can

FIGURE 7. Typical Ballooned-Out Sella of a Pituitary Adenoma, with Erosion of the Posterior Clinoid Processes.

results are better than the published results of many other clinics.

A person discussing a paper should stick to the paper and should not bring up some new topic; nevertheless, I am going to branch out somewhat. Dr. Horrax said little about the cystic hemangiomas. He stated that as a rule they are favorable cases, easily missed and rather difficult to handle. That is true. The patients frequently come to us without a diagnosis, and we often miss the diagnosis ourselves. Mistakes would be less frequent if careful examination of the whole of the fundus were the rule, particularly in cases of tumor of the cerebellum. Hemangioma of the retina is often associated with hemangiomatous cyst of the cerebellum.

Dr. Horrax spoke of the higher mortality in cases of malignant tumor. That has been our experience also. It

secrete fluid. I have long thought that the fluid must come from the capillary bed in the mural nodule and not from cells of the nervous system. I wonder whether on careful study the mural nodules of fibrillary astrocytomas show some relation to the capillary hemangiomatous type that Dr. Mixter has spoken about, and whether Dr. Horrax considers the fibrillary astrocytomatous cysts to be burned-out or partly burned-out hemangiomas.

DR. DONALD MUNRO, Boston: Dr. Horrax's presentation and figures are most encouraging. I do not know when I have heard any set of figures that stimulated me more. It is wonderful to have such an encouraging report come out about brain tumors, and I am sure all of you who see an occasional brain tumor realize that such encouragement is long overdue.

I should like, however, to present another point of view—that of the surgeon who sees brain tumors in the course of all the varied mixture of crises that comes into a non-specialized clinic. I do not see many patients with brain tumors; they usually have other diseases of the central nervous system. Those that I do get are able to have

cludes a type of tissue that is blastomitous; the patient's life expectancy is only a year. That is well known, but what has not been so well recognized and brought out so clearly before is that mixed with the unfavorable type of cell there may be a very favorable type, and unless a great amount of tissue is provided for the pathologist to

FIGURE 8 Stages in the Operation for Removal of a Pituitary Adenoma

Through a right frontal bone flap the dura is retracted and incised exposing the tumor between the optic nerves. The contents are removed by spoons and suction. The capsule is excised down to the sella (Horrax reproduced by permission of the publisher)

been neglected or to have been undiagnosed for a long time. I should accordingly like to emphasize a point that I know Dr. Horrax believes in but did not have time to speak of and that is based on my experience with this particular group of tumors.

I have had 142 verified tumors. Fifty-nine per cent were gliomas. I have not classified them into favorable and unfavorable types, but that is a higher percentage than one would expect in a more segregated group of tumors.

A recent study has demonstrated that if any glioma in

examine a favorable prognosis may be given whereas in fact the tumor is an unfavorable type of tumor.

This leads me to the first point to be emphasized, namely that it is in my opinion impossible to make an adequate prognostic diagnosis of any given brain tumor unless that tumor is exposed at operation.

Another important thing and another reason for exposing all brain tumors or suspected brain tumors is that the ultimate end result of many of these cases depends in part at least, on the situation of the tumor. Many favorable types of tumors have a bad prognosis because

they are so situated that they cannot be removed without producing death or a very bad invalidism from paralysis; therefore, what I should like to emphasize, and what I am sure Dr. Horrax would have emphasized had he had time, is that if a patient is suspected of having a brain tumor, particularly when there is any suggestion of localization, one should not neglect to provide that patient

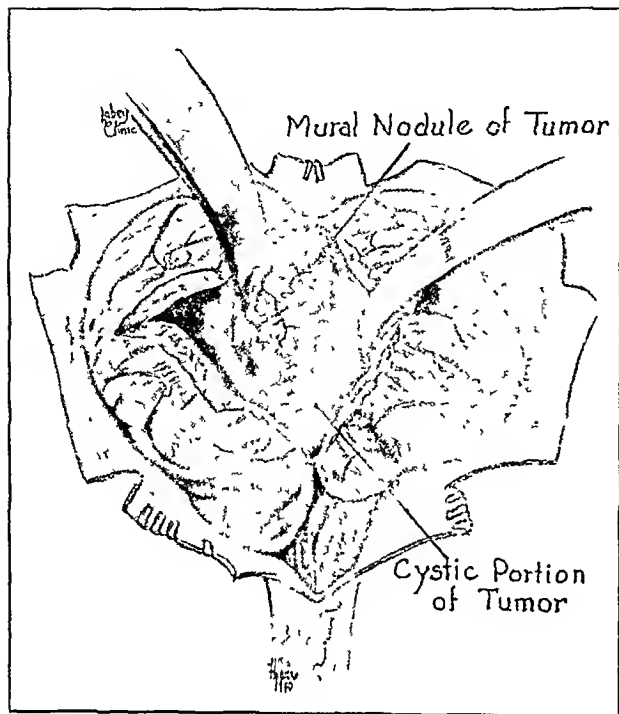

FIGURE 9. *Cystic Astrocytoma of the Cerebellum, Showing the Solid Portion of the Tumor in the Cyst Wall.*

with the ultimate in diagnostic means; that is, all such patients should be explored early and thoroughly. If the tumor is found, large amounts of the tissue should be taken out so that the pathologist can, in his turn, give a thoroughly accurate and adequate estimate of the prognosis. Only then has one the right to tell the patient that he is going to be well, or that he is going to die in any given time. Unless one has that specialized information, one is as liable to be wrong as to be right about this vital point.

DR. THOMAS H. LANMAN, Boston: I am speaking for Dr. Franc Ingraham, of the Neurological Service at the Children's Hospital. He has been very anxious to bring out one point with which he has been greatly impressed in dealing with brain tumors in children.

Dr. Horrax has mentioned the favorable nature of astrocytomas. Dr. Ingraham has found that these constitute a rather high percentage of the tumors found in children. He believes very strongly that the diagnosis between astrocytoma and medulloblastoma cannot be established without exposing the tumor. He is therefore convinced that exploration should always be done, and that radiation without a previous accurate diagnosis will result, and has resulted, in dangerous delay. The patient with astrocytoma has a fairly good prognosis after surgical removal of the growth.

DR. HORRAX (closing): In regard to Dr. Cutler's question concerning the cells and their secretion in the astrocytomatous cysts, I have not made a special study of this problem. The tumors grossly are usually so different that it would lead me to suspect that they must be somewhat different in their histologic aspects, though doubtless all have the same function of producing fluid. I assume that the fluid must come from some product generated in the cells, rather than that it is an influx from the cerebrospinal fluid, because the cerebrospinal spaces do not connect with the cysts. Many hemangiomas cysts, but not all, have a bright-red nodule. An astrocytomatous cyst has a brownish and almost always a much larger nodule, but I have not studied the histology of the cells from the standpoint of secretory activity, so that I cannot say whether they are alike in this respect. They are both very favorable and not infrequent lesions, however.

Dr. Mixer's prophecy in regard to the ability to diagnose malignant tumors will undoubtedly come true, but we certainly have not reached that stage yet. Many people are doing various types of study to see if they can diagnose malignant tumors, and differentiate a glioblastoma from some of the more benign types, but not until we have reached that stage can we dispense with exploring, as Dr. Munro has said. I think, as Dr. Cushing did, that one must also do a very radical operation; in fact, I always try to take out all the tumor tissue possible, because, as Dr. Mixer and Dr. Munro have emphasized, many tumors will be of the mixed type and may have a prognosis of three, four, five or even ten years of perfectly good health before the symptoms recur.

I agree with Dr. Ingraham about the astrocytomas and medulloblastomas. The latter do respond to x-ray treatment, but there is no sure way of diagnosing them beforehand. When one has made a diagnosis of a tumor in a child, what to do is another question. One can take out some of it or remove as much as possible, but it is very difficult, at least in our hands, always to be sure preoperatively whether one is dealing with an astrocytoma or a medulloblastoma.

TUBERCULOSIS OF THE CECUM*

RALPH ADAMS, M.D.,† AND LANGDON J. PARSONS, M.D.‡

BOSTON

TUBERCULOSIS of the cecum is an uncommon disease in the wards of the Massachusetts General Hospital, where 79 cases of intra-abdominal tuberculosis have been diagnosed from 1924 to 1939. Thirty-eight of these are eligible for classification as tuberculosis of the cecum.

Attention was drawn to a consideration of this disease because the treatment of tuberculosis of the cecum in general hospitals seems to be poorly standardized. The question of whether surgical approach to the disease has any advantage over prolonged rest and supportive treatment, as in the pulmonary form, appears debatable. Naturally, the surgeon accepting a patient will be guided in his technical procedures by the extent and nature of disease encountered, but there is little agreement as to the best method to follow in a favorable case.

The usual history was one of infrequent colicky pain without radiation, centered around the umbilicus or localized in the right lower quadrant. The pain was associated with varying degrees of distention and was often relieved by pressure over the abdomen and by the passage of flatus or bowel movement. It seemed to have little relation to meals. Frequently there was a vague sense of discomfort in the right lower quadrant. As the symptoms became more frequent and severe, the pain was associated with vomiting. The severity of the pain and vomiting depended, in large measure, on the degree of obstruction. Increasing constipation, with failure to obtain relief by catharsis, and an increasing reliance on enemata were natural sequelae. Blood or mucus was or was not found in the stools, depending on the type of tuberculous process. The ulcerative form was less common than the hyperplastic in the older patients, and this fact probably explains the infrequency of melena in this age group. The changes observed in bowel habits tended toward diarrhea in the younger patients and almost invariably toward constipation in the older ones. All these symptoms were in the nature of obstructive episodes of gradually increasing severity. This is shown by the duration of illness, which began, for the most part, from six months to one year preceding admission. Rarely were the symptoms acute.

A train of generalized systemic complaints ac-

companied the localized obstructive symptoms. Ninety per cent of the cases had lost from 15 to 45 pounds within a year. The appetite was but little disturbed. Half the patients had symptoms referable to the lungs, although in several cases with no symptomatic evidence of pulmonary tuberculosis disease in the cecum had reached an advanced stage. All the patients who complained of thoracic symptoms were found to have advanced pulmonary tuberculosis. Contrary to expectation, only 19 of the 38 patients had physical signs of disease in the lung. This was of long duration in most cases, was readily noted on physical examination and was confirmed by x-ray examination.

An irregular mass with tenderness and spasm was observed in half the cases. It was characteristically extensive and fixed to the right lateral abdominal wall. Slight elevation of temperature (99.5 to 101.0°F.), with a correspondingly elevated pulse, was a common finding. The degree of emaciation depended on the extent of disease. The abdomen was distended in 7 cases, in each of which the patient had a mass in the right lower quadrant.

In contrast to the usual observations in other right-sided colonic lesions, notably carcinoma, only slight pallor and anemia were noted, despite the degree of emaciation. The red-cell count was never below 3,800,000, even in the advanced cases, and the hemoglobin reading was rarely below 70 per cent. A slight leukocytosis, from 13,000 to 15,000, with a rise in polymorphonuclear cells to 80 per cent, was commonly observed, as was an increase in the mononuclear cells to around 10 per cent. A positive guaiac test in the stools was not very helpful, for although 44 per cent of the cases were far advanced, positive examinations were reported in only 4 cases. Tubercle bacilli were demonstrated in the sputums of 13 cases.

The radiologists frequently observed spasm of the cecum to the point of incomplete filling, associated with a fixed, rigid, irregular and deformed ascending colon in many cases. These findings are often referred to as the "Steirlin defect." Attempts to confirm the findings of barium enema by a gastrointestinal series usually failed to provide additional information. A correct diagnosis was not made in 2 cases on the first admission because the gastrointestinal series was negative and a barium enema was not given. The commonest error in x-ray interpretation was to confuse the

‡Assistant in surgery, Harvard Medical School, assistant surgeon, Massachusetts General Hospital.

lesion with carcinoma of the cecum. The failure to find positive evidence of tuberculosis, either on physical examination or by fluoroscopy of the chest, contributed to the faulty diagnoses. A characteristic x-ray report reads as follows: "Tuberculosis unlikely because of negative chest findings." One third of the patients over thirty-five years of age, and nearly half the patients, had the disease in the absence of clinical or x-ray evidence of pulmonary disease.

CASES OPERATED ON

Seventeen patients were subjected to a laparotomy. These cases were of the greatest help in determining the proper course of future treatment.

Exploratory Laparotomy

Four patients had only an exploratory laparotomy, with the added excision of a mesenteric lymph node for biopsy in 2 cases.

CASE 1. A 25-year-old woman was found to have tuberculous colitis in addition to cecal involvement. The appendix had been removed at another hospital, and a microscopic diagnosis of tuberculosis was available. The evidence was thought insufficient for resecting the cecum, since rectal bleeding, from which the patient suffered, might be arising from a lower point in the colon. Only a calcified gland was removed. She made a good convalescence and recovered on a regimen of rest.

CASE 2. A 28-year-old man was explored, with a pre-operative diagnosis of acute appendicitis. A thickened, inflamed cecum was found, adherent to the right lower abdominal wall. The appendix could not be found and hence was not removed. A necrotic mesenteric node was excised for biopsy. The patient made an uneventful recovery.

CASE 3. A 45-year-old man was operated on following a diagnosis of appendiceal abscess. Tuberculosis was recognized as the cause of the cecal mass. The appendix was not removed. One year later, after following a hygienic regimen for several months, he was well and working.

CASE 4. A 39-year-old woman was an excellent subject for study, because progress of the disease was visualized at successive operations. Active tuberculosis of the intestines, with adhesions around the cecum, was seen at the first operation, done for a pelvic disorder. Inactive lesions were seen at a second laparotomy on the pelvic viscera. The patient is well and working.

It should be noted that no untoward effects followed the removal of mesenteric nodes in either Case 1 or Case 2. Cases 2, 3 and 4 illustrate the wisdom of noninterference. The appendix was not molested, and no sinuses developed. The patients recovered on a sanatorium regimen and are now arrested cases. Case 3 particularly emphasizes the courage required to withhold appendectomy, and the successful result that ensued.

Ileostomy

Three cases had an ileostomy only. Each had extensive intestinal disease, with mechanical ob-

struction in the right lower quadrant. Two were relieved of their obstruction but died of progressive tuberculosis. The third patient was dramatically relieved of pain, distention and diarrhea but died of a pulmonary embolus on the sixteenth post-operative day. These 3 cases were beyond the reach of hopeful therapy. They do illustrate the relief and comfort that may come from palliative operations on even badly ulcerated, tuberculous bowel. The principle is, of course, the same as that sometimes applied in ulcerative colitis. Ileostomy should be reserved for extensive cases with obstruction or profound irritative symptoms, when active disease in the lower bowel makes anastomosis doomed to failure.

Anastomosis Only

Three patients had a sidetracking anastomosis, 2 in addition to appendectomy.

CASE 8. A 33-year-old man first had drainage of an appendiceal abscess. Three months later, he was readmitted with a fecal fistula and a mass in the right lower quadrant. There was advancing right apical pulmonary disease, and a spastic, nonfilling, deformed cecum was demonstrated by x-ray examination. Palpable involvement of the bowel extended to the mid-transverse colon at the second operation. The process was too extensive for resection. An ileosigmoidostomy was done. The sinus continued draining, and the patient was sent to a sanatorium. No new sinuses developed, but he died several months later of tuberculosis.

CASE 9. A 28-year-old woman was explored for sub-acute appendicitis. A mass surrounded the cecum. The appendix was removed, and the stump buried. An ileo-transverse colostomy was done. A sinus developed from the tip of the cecum within 3 months. This sinus healed on sanatorium treatment within a year, and the patient was discharged as an arrested case, 18 months after the onset of disease.

CASE 10. A 60-year-old woman with far-advanced disease had an ileocolostomy but died 5 weeks later of debility and retroperitoneal sepsis. Post-mortem examination showed tuberculous colitis and ileitis, and retroperitoneal abscess. Clinically, the patient had been thought to suffer from carcinoma of the cecum.

The error in Case 8 was in expecting an actively infected bowel to heal. The second operation probably can be regarded only as an additional burden on an already overtaxed patient. Case 9 was one with relatively quiescent disease. The anastomosis was done between nondiseased loops of bowel and remained secure. An ideal situation existed for general rest in a sanatorium and for local rest of the diseased part by the sidetracking anastomosis, and the sinus that developed from the active focus in the cecum closed quickly. A sidetracking anastomosis probably offers the best hope of arrest in such a case, characterized by an obstructive mass and persistent localized activity. The anastomosis should be done between unin-

involved portions. Suture lines in the involved bowel frequently leak and are followed by sinus formation. An opening into the actively diseased cecum also invites sinus formation. Appendectomy increases the likelihood of this complication.

Resection

Resection and anastomosis were done in 7 cases.

CASE 11 A 55 year old carpenter entered the hospital with cramplike lower quadrant pain, and increasing constipation of one year's duration. There was a tender 6-cm mass in the right lower quadrant. A barium enema showed a constant filling defect in the cecum. The resected mass contained tuberculous pus. The patient had a good immediate convalescence and was lost from follow-up. Probably he died from his active pulmonary tuberculosis with cavitation.

CASE 12 A 38 year old unemployed Chinese entered the hospital in 1931, complaining of recurrent crampy abdominal pain and a loss of weight of 30 pounds within a year. A firm, tender, irregular mass filled the right lower quadrant. The chest was normal on physical and x-ray examination. A spastic cecum surrounded by a mass was demonstrated by barium enema. There was a 7.5-cm area of constriction in the proximal transverse colon. Tuberculosis was thought unlikely because the chest plate was negative. Two operations for incision and drainage of a pericecal abscess were done prior to the main operation which consisted of resection of the terminal ileum, ascending colon and first portion of the transverse colon. A lateral anastomosis was done. These operations revealed the abdomen to be free of disease except for the right lower quadrant and the right iliac fossa, where a posterior perforation had occurred from the cecal mass. The terminal ileum was infiltrated and thickened. Pathological examination revealed tuberculous ulceration of the cecum, ascending colon, and the distal 5 cm. of the ileum. The patient made a good recovery and is now well and working.

The diagnosis before and after operation in Cases 11 and 12 was thought to be carcinoma of the cecum. Involvement of the ileum should have suggested tuberculosis to the surgeon. The fact that the remainder of the abdomen was free of disease, however, made the diagnosis of tuberculosis unlikely. Undoubtedly, it is better to resect an active tuberculous cecum occasionally than to leave in place a carcinomatous cecum that is favorable for resection and cure.

CASE 13 A 58 year old housewife was admitted in 1935, complaining of two attacks of cramplike abdominal pain within a year. There was a tender fixed mass in the right lower quadrant. A chest plate showed contracture of both apices consistent with inactive tuberculosis. A barium enema suggested ileocecal tuberculosis because of widespread mucosal destruction and scarring of the cecum and the ileocecal valve. Scirrhus carcinoma also was suggested because lack of spasm and lack of ileal involvement made the diagnosis of tuberculosis uncertain. Absence of change in bowel habits and freedom from blood favored tuberculosis as against carcinoma of the cecum. The surgeon's opinion was confirmed by pathological examination which showed ulcerative and hyperplastic tu-

berculosis of the ileum and the cecum. The patient is well and working.

CASE 14 This patient, a 44 year old housewife gave a history of various isolated episodes of diarrhea for many years. She had lost 23 pounds after an increase in diarrhea 6 months previously. There was occasional blood streaking of the stools. There was tenderness in the right upper quadrant. Chest examination was negative but x-ray examination of the chest was not made. The barium enema met definite obstruction just below the hepatic flexure and showed deformity and narrowing of the cecum and ileocecal valve. The rugae were obliterated. The findings were considered typical of cancer. Carcinoma of the cecum was the only diagnosis considered until the resected specimen was examined histologically and tuberculosis was found. Extensive old abdominal adhesions were the only clue to the diagnosis at the time of operation. The appearance of the local lesion was entirely consistent with carcinoma. There were acute intestinal obstruction and abdominal abscess postoperatively. She has continued to have recurrent attacks of diarrhea, with mucus and occasional blood, since operation six years ago, and is unimproved. Presumably chronic tuberculous colitis has continued to cause her symptoms.

CASE 15 An 18 year old boy was admitted complaining of abdominal cramps, malaise and anorexia of 6 months duration. There were mucous diarrhea without blood and a loss of 25 pounds in weight. The chest was clear by physical examination, but on x-ray examination the hilar shadows were increased. The patient was emaciated. There were slight tenderness and spasm in the right lower quadrant. A barium enema showed spasm of the ileum and cecum. An abscess surrounded the cecum. The ileum was thickened and dilated. The walls of the cecum were red and granular, and there were two narrowed areas in the ascending colon. Right colectomy and ileotransverse colostomy were done. Pathological examination showed the bowel walls to be thickened and the mucosa to be red granular and superficially ulcerated. The diagnosis was established microscopically. The patient failed to close a postoperative cecal fistula during several months' rest in a sanatorium. He was discharged against advice with a fistula but with great improvement over his preoperative condition.

In Case 15, the boy improved postoperatively on a sanatorium regimen, it is true, but several factors suggest that operation might wisely have been postponed indefinitely, and that he might have done equally well on a medical regimen exclusively. The preoperative diagnosis was probable tuberculosis. The alternative diagnoses of appendicitis and carcinoma could be excluded with reasonable certainty on the clinical and x-ray data and because of a white cell count of 10,000 and 70 per cent polymorphonuclear cells. The patient was emaciated and in poor condition for any elective operation. The likelihood of activity and poor results because of youth might have been considered more serious contraindications than they apparently were. The cecal fistula was an added burden. The improvement postoperatively is more likely due to the good sanatorium care than to the operation.

CASE 16. A 44-year-old American chemist was admitted in 1937, complaining of increasingly frequent attacks of abdominal pain accompanied by nausea, vomiting, and occasionally diarrhea, for five years. The episodes could be avoided by a regimen of mineral oil and liquid diet. He had had pulmonary tuberculosis 19 years previously, with a recurrence 13 years previously. He was undernourished. There was a movable, slightly tender mass in the right lower quadrant. A barium enema showed a filling defect in a shortened, scarred cecum. The terminal ileum was dilated but could not be filled with barium. A right colectomy was done. The convalescence was uneventful, and the patient is now well and working, 2 years after operation.

CASE 17. A 55-year-old woman was well for 7 years following a right colectomy, anastomosis and sanatorium convalescence in 1926. The procedure was done for purely obstructive symptoms caused by inactive constricting tuberculosis and scarring of the cecum. Tuberculosis of the lung had existed fifteen years before admission to the hospital, with clinical arrest, and an x-ray plate of the chest showed healed tuberculosis at the right apex. Presumably, there was also tuberculous enteritis thirteen years previously. Poverty in 1933 caused undernutrition, and there have been recurrent periods of diarrhea and pain since that time. There is now a mass in the left upper quadrant, but debility and old age preclude consideration of further operative procedure.

The patients in Cases 16 and 17 represent the type that obtained most benefit from surgery. In contrast to the youth in Case 15, their tuberculosis was quiescent, the disease was localized and the symptoms were purely obstructive in origin. Consequently, a direct attack on the involved cecum was tolerated. In the peritoneal cavity, as in the lung, pleura or bone, surgical attack on active tuberculosis results usually in disappointment for the surgeon and grief for the patient. It seems futile to attempt extirpation of active disseminated colonic tuberculosis. In cases properly selected for resection, the suture lines have caused little trouble. No unusual principle is involved in selecting a site for anastomosis, beyond the choice of a bowel free from gross evidence of previous involvement.

In summary, then, of the 7 cases on which resection was done, 3 patients are well and working, 1 is improved, 1 was relieved for seven years, after which the disease recurred, 1 was unimproved and 1 presumably died of generalized tuberculosis.

CASES NOT OPERATED ON

Twenty-one patients remain on whom no operation was done. In 9 of these, advanced generalized tuberculosis—of which cecal disease comprised only one major part—precluded consideration of any operative procedure. All 9 are dead.

Ten patients had extensive disease in the cecum and frequently elsewhere, but a hygienic regimen was advised instead of operation after weighing

the merits of each case. Three of this group of 10 grew steadily worse until death, and a fourth is near death from pulmonary tuberculosis. Three patients have had arrest of their disease but remain unemployed. Three patients are well and working. Two of these 3 deserve special mention because they had associated pulmonary disease requiring thoracoplasty. No operation was performed until a rigid sanatorium regimen had caused the intestinal lesions to become quiescent; the thoracoplasties were then done. The intestinal disease remained quiescent. Complete clinical recovery resulted in each case.

An operation on one focus of tuberculosis will often cause any active focus elsewhere in the body to become worse. Experience has proved that this relation is unusually close between the lungs and the intestinal tract. A patient with a single lesion should demonstrate ability to localize it, and a person with two lesions should demonstrate ability to arrest one of them before being considered for elective operation. That this conservatism on the part of thoracic surgeons is no idle fear is indicated by one of the cases mentioned above as arrested but unemployed, which began a fulminating ileocecal tuberculosis immediately after a second-stage thoracoplasty.

Two patients who were urged to have operation and refused further illustrate the reparative processes that may occur under favorable hygienic conditions.

CASE 18. A 24-year-old man was seen in 1931 with diarrhea, periumbilical pain, night sweats, weakness and passage of mucus in the stools. The cecum and terminal ileum were spastic, poorly filling and tender. After two years of sanatorium care, the lesion could no longer be seen by x-ray examination. The patient did work as a cabinetmaker for one year, and the symptoms recurred. The disease again was shown by x-ray examination, and operation was advised. Again it was refused. A hygienic regimen was established. The patient was seen in 1934, 3 years later, when he was gaining weight and doing light work. A gastrointestinal series and a barium enema showed a deformed cecum but an apparently healed gastrointestinal tract. There was no pulmonary disease. He was last seen in 1939, eight years later, in "the best condition in many years."

CASE 19. A 60-year-old woman complained of increasing distention, intermittent pain in the right lower quadrant, belching of gas and flatus for one year. The pain had become colicky in the few days preceding entry. There was a chronic cough of many years' duration. Subacute obstruction subsided on the ward. Investigation disclosed a collapsed right middle and right lower lobe. A barium enema showed an extensively deformed and scarred cecum, with a very narrow ileocecal lumen. The rest of the bowel looked normal. A proctoscopy was negative. The sputum was negative for acid-fast bacilli. There was no blood in the stools. The patient was strongly advised to have an operation for subacute intestinal ob-

struction, probably due to tuberculosis of the cecum. Thus she absolutely refused to consider. She has led a quiet life at home on a soft bland diet and has had no further gastrointestinal symptoms. She can eat anything she wishes. There is one bowel movement a day without mucus or blood.

SUMMARY AND CONCLUSIONS

The chief value of reviewing a small group of patients with tuberculosis of the cecum is that these cases represent the problem as seen in the community, inasmuch as they are drawn from the wards of a general surgical hospital. For example, it has long been an impression, gathered largely from reports of tuberculosis sanatoriums, that the absence of clinical or x ray findings of pulmonary tuberculosis tends to rule out tuberculosis of the cecum, thereby contributing to the diagnosis of carcinoma of the cecum, with which it is most often confused. Yet 19 of the 38 cases reviewed in this series failed to show either clinical or x ray evidence of tuberculosis in the lungs. Another point of interest in the differential diagnosis between carcinoma and tuberculosis may be found in the relatively normal blood picture, despite marked cachexia, commonly observed in tuberculosis, in decided contrast to the profound anemia often present in carcinoma of the ascending colon, even in its earlier stages.

Despite these observations and the fairly characteristic x ray picture of tuberculosis of the cecum when spot films are employed, the differential diagnosis between tuberculosis and carcinoma cannot always be made. Exploration is, therefore, indicated. The problem, then, is in proper evaluation of the pathologic lesion, which in most cases is extensive. Involvement of the terminal ileum contributes to the diagnosis of tuberculosis. The commonest error is the failure to estimate adequately the degree of activity of the tuberculous process after carcinoma has been ruled out. Extensive surgery involving resection of the right colon, in the presence of active disease, encounters risk of failure. Temporizing procedures, such as appendectomy, frequently produce distressing fistulas. When sanatorium care has followed exploration alone, excellent results have been obtained. Surgical intervention is theoretically sound only to relieve acute obstruction or to remove obstructive sequelae of an arrested infection, and in practice the theory is fairly well substantiated. A sanatorium regimen should precede surgical intervention in practically every case, because tuberculous activity can be halted only by tissue resistance, and because rest is the best aid to healing.

VITAMIN C SURVEY IN DIABETES*

LOUIS B. OWENS, M.D.,† JACKSON WRIGHT, M.D.‡ AND EDNA BROWN, M.S.§

CINCINNATI

THE relation of vitamins to human nutrition has recently been widely studied, and the basic importance of certain vitamins in cellular metabolism has become evident. In a metabolic disease such as diabetes, there is a profound disturbance of carbohydrate storage and utilization, and the effect of vitamins may become particularly important. Possible vitamin B inadequacies in diabetic patients were discussed in a previous paper,¹ and the effects of administering various vitamin B fractions to well controlled diabetic patients were reported. No evidence of inadequacies was found.

This paper reports a survey of the vitamin C

status of 125 diabetic patients to determine how much vitamin C is actually eaten, and to see what relation exists between vitamin C and the severity of the disease.

Sebesta, Smith, Fernald and Marble² have recently published the results of a study of the vitamin C status of 49 diabetic patients who were observed at the New England Deaconess Hospital. Their results indicated an excellent state of vitamin C nutrition. Only 1 patient showed a fasting blood ascorbic acid level below 0.40 mg per 100 cc, 12 patients (24 per cent) showed levels between 0.40 and 0.80 mg, and the remaining 36 (74 per cent) had blood levels over 0.80 mg. On the five-hour-1000 mg saturation test,³ only 13 (26 per cent) showed an excretion under 400 mg. The authors suggested that the values were not representative because their patients were of the higher economic groups, and that the findings of a large public clinic might be quite different.

The Diabetic Clinic of the Cincinnati General

*From the Department of Internal Medicine and the Laboratory for Experimental Medicine, University of Cincinnati, and the Diabetic Clinic, Cincinnati General Hospital.

†This study constitutes part of the activities supported by the Espy Fund for research in diabetes.

‡Instructor, Department of Internal Medicine, University of Cincinnati, Director, Diabetic Clinic, Cincinnati General Hospital.

§Research fellow in diabetes, Department of Internal Medicine, University of Cincinnati.

Research assistant, Department of Internal Medicine and the Laboratory for Experimental Medicine, University of Cincinnati.

Hospital offers an unusual opportunity to study the vitamin C status of patients in low economic groups. It is entirely a charity clinic, supported by city and county funds; no patient who can afford the services of a private physician is admitted for treatment. Over 30 per cent of the patients are on direct relief, 20 per cent are supported by private industry, and the remainder are on WPA, old-age pension, veterans' benefit or some other form of charity.

Even though the food expenditure in our clinic averages only \$2.10* a week, an attempt is made to design all diabetic diets so that they are adequate in protein, minerals and vitamins. We believe that any dietary lack, particularly with reference to the vitamins, is more a failure of co-operation or a lack of funds than an inherent fault of the diet. Diet classes are held weekly to acquaint diabetic patients with the benefits of raw fruits and vegetables, in the hope that whenever possible they will select foods high in vitamin content.

METHOD OF STUDY

One hundred unselected "old" diabetic patients, who were being followed regularly in the clinic, were studied during a period extending from February to June, 1940, and 25 "new" patients with no previous treatment were also observed. Blood samples were taken either fasting or when, by special arrangement, no food containing vitamin C had been eaten for breakfast. The method of Farmer and Abt⁴ was used for the blood ascorbic acid determination. The dye (2,6-di-chloro-phenol-indophenol) was refrigerated in a glass-stoppered brown bottle and was standardized against a known solution of Cebione† at intervals of two to three weeks.

Thirty-five cases were selected for an estimation of the vitamin C content of the diet. Patients were asked to keep a daily record of the type and amount of vegetables, fruit and meat eaten. The sizes of the portions were recorded in common household measures. The diets were first evaluated for *dependable* sources of vitamin C, such as citrous fruits, tomato juice and raw vegetables, and then for *uncertain* sources, such as cooked fruit and vegetables. The table compiled by Bessey⁵ was used for estimating the vitamin C content of the various foods. The small amounts in milk and meat were disregarded. Dependable and uncertain sources were calculated separately and then divided by the number of days the diet was ob-

served, so that the final figures represent the average daily intake from all sources.

Individual diets were prescribed for each patient, the daily intake ranging from 920 to 2300 calories. It is the policy of the clinic to prescribe an "average" amount of carbohydrate in diabetic diets. Fifty per cent of the patients were allowed a carbohydrate intake between 120 and 150 gm.; in 25 per cent it was over 150 gm. and in 25 per cent under 120. Only four diets had a carbohydrate intake under 100 gm., and only two were over 200.

Ophthalmoscopic examinations were made on all patients, with particular attention to the presence of lenticular opacities, the state of the vessels, hemorrhage, exudate, atrophy and pigmentation. When retinitis was suspected, an eye consultation was obtained. Clinical evidences of scurvy were sought by examination of the gums. Changes in the gums were thought to be significant if they seeped blood by moderate pressure with a throat stick, or if there was a history of repeated bleeding following the use of a toothbrush. If gums that bled easily were also spongy and hypertrophic, a capillary-resistance test was made by placing the blood-pressure cuff at 30 mm. and inflicting mild trauma in the antecubital space. When boils, open ulcers, carbuncles, incipient gangrene or osteomyelitis was present or had recently occurred, infection was considered significant.

So that adequate controls might be supplied, 50 nondiabetic patients were taken at random from the general medical clinic. No patient on a therapeutic diet was studied. The method of collecting the samples was the same as that for the diabetic patients.

RESULTS

Results of the blood ascorbic acid determinations in diabetic patients and in the controls, and comparisons of levels in various groups are shown in Table 1.

The status of the 100 "old" diabetic patients was found to be considerably better than that of the controls, but was still far below optimal levels. Sixty-three per cent had fasting blood levels below 0.80 mg. per 100 cc., and 35 per cent had levels below 0.40 mg. It was believed that if diet instruction had not been given, the selection of food would have been no different from that of the controls, and that the blood ascorbic acid level would have been in the same low range as in this uninstructed group.

The blood ascorbic acid levels of "new" diabetic patients fell somewhat lower than those of the "old" diabetic patients, but were better than those of the controls. Seventy-six per cent were below

*The recent initiation of the food-stamp plan for Cincinnati relief clients, and the placing of citrous fruits and fresh vegetables on the surplus-commodity list, may considerably simplify the dietary problems of diabetic patients who are on relief.

†The Cebione used in this study was supplied through the courtesy of Merck and Company, Rahway, New Jersey.

0.80 mg. per 100 cc., and 48 per cent were below 0.40 mg. It was again believed that the factor of food selection influenced the results, and that the group as a whole would improve when adequate dietary instruction had been received.

One of the most striking findings in the whole study was the exceedingly low level of blood vitamin C found in the 50 nondiabetic patients. Ninety per cent were below the optimal level of 0.80 mg. per 100 cc., and 68 per cent were under the generally accepted critical level of 0.40 mg. The economic status of the nondiabetic patients was no better than that of the diabetic patients. Left to

to interest the wives of our patients in the lectures on diet instruction.

There was no relation between blood ascorbic acid and age or race of the patients. Thirty-two per cent of the patients were over sixty years of age and showed about the same distribution of values as the whole group. The average for 67 white patients was practically the same as that of 33 colored patients.

Dietary Intake

Diet analysis has proved to be only a fair means of studying vitamin C nutrition. Although the reliability of the patient must be taken into consid-

Diabetic patients with cataracts	34	7	20	11	32	16	48

their own selection on a limited allowance for diet, they chose cheap foods that happened to have a low vitamin C content. In spite of these low chemical findings, no cases of scurvy were found among the nondiabetic patients.

INFLUENCE OF VARIOUS FACTORS ON BLOOD VITAMIN C LEVELS

Sex, Race and Age

The male diabetic patients had lower levels of blood ascorbic acid than the female patients. Analysis of the diet showed that the former consumed foods low in vitamin C (cooked vegetables and meats), whereas the latter were more inclined to eat foods that supplied a good source (salads, raw vegetables and fruit). Furthermore, the women were more likely to go home and prepare the food about which they had been instructed, but the men had to convey the diet instructions to their wives. In only a few cases have we been able

to interest the wives of our patients in the lectures on diet instruction.

There was no relation between blood ascorbic acid and age or race of the patients. Thirty-two per cent of the patients were over sixty years of age and showed about the same distribution of values as the whole group. The average for 67 white patients was practically the same as that of 33 colored patients.

Dietary Intake

Diet analysis has proved to be only a fair means of studying vitamin C nutrition. Although the reliability of the patient must be taken into consid-

eration, there is also a marked variation in actual vitamin C content of foods as they reach the table. The season of year and the length of time that the food is cooked both alter the amount of available vitamin C. Of the 35 diet analyses made, only two thirds showed a direct relation between the intake of dependable amounts and the blood ascorbic acid. Among the remaining third, 6 patients reported diets with adequate amounts of vitamin C, but showed low blood ascorbic acid levels; 5 showed little or no dependable sources but still had reasonably normal blood levels. No relation at all could be found between *uncertain dietary* sources of vitamin C and the blood level.

If a diet is low in calories, it does not necessarily follow that it is low in vitamin C. Foods of high caloric content, avoided in reduction diets, usually have less vitamin C than foods of low caloric content. Vegetables, fruits and salads high in vitamin C are substituted for bread and fats that have a

lower content. Of 12 patients on reducing diets of 1200 calories or less, one third were found to have blood ascorbic acid levels under 0.40 mg. per 100 cc., and one third had levels over 0.80 mg. This was about the same distribution as that for diabetic patients who were not on reducing diets.

Duration and Severity of the Diabetes

It appears that the longer a patient has diabetes, the higher his ascorbic acid level becomes. Non-diabetic patients had lower ascorbic acid levels than "new" diabetic patients, and "new" patients lower levels than "old" diabetic patients. Forty-four per cent of the patients who had had diabetes for five years or longer were found to have levels of over 0.80 mg. per 100 cc.; only 24 per cent were under 0.40 mg. Seven out of 8 diabetic patients who had blood ascorbic acid levels over 1.30 mg. had been clinic patients for five years or longer. Diet instruction most probably accounts for these findings. The longer a patient has diabetes, the oftener he hears lectures on diet selection, and by dint of repetition, he learns to choose foods that, among other things, are high in vitamin C.

The state of diabetic control and the level of the blood sugar at the time the blood sample was taken had no relation to the blood ascorbic acid, nor did the administration of insulin in any type or amount have any effect on the vitamin C status of the patient.

It has been stated that there is an increased demand for vitamin C during infections,⁶ and that a low vitamin C level of itself tends to delay wound healing.⁷ To find any relation between the two, evidences of either recent or actual infections were sought. No significant relation was discovered; just as many patients in a good state of vitamin C nutrition had pyogenic processes as did those who had chemical scurvy.

Certain Eye Conditions

Bellows⁸ has reported lower vitamin C levels in patients with cataract than in control patients of the same age groups and economic status. Furthermore, he has been able to produce cataracts in guinea pigs by feeding them diets low in vitamin C. The findings in our group of diabetic patients with cataracts failed to support such a contention; 48 per cent had blood vitamin C levels over 0.80 mg. per 100 cc. whereas only 20 per cent had levels below 0.40 mg. Some of the highest levels recorded were found in cataractous patients.

Patients with retinitis, either diabetic or arteriosclerotic, showed a slightly lower ascorbic acid level than the other diabetic patients observed. Among 125 patients, both "old" and "new," 17

cases of retinitis were found. Of these, only 24 per cent had a blood level over 0.40 mg. per 100 cc., compared with 34 per cent for the whole group. Although these findings are lower than the average figures, they are not different enough to be significant.

Bleeding, Infected and Scorbutic Gums

Over half the diabetic patients studied were edentulous. Among the remaining patients, bleeding gums were found oftener in those who had low levels of ascorbic acid. Forty-eight per cent of diabetic patients with ascorbic acid levels under 0.40 mg. per 100 cc., had bleeding gums, whereas only 26 per cent with levels over 0.80 mg. showed this sign. On the other hand, many patients in an excellent state of vitamin C nutrition had gums that bled easily, and normal gums were found in patients whose ascorbic acid levels were close to zero. Low vitamin C was therefore not considered an etiologic factor in the bleeding gums so frequently found in clinic patients.

The incidence of pyorrhea was approximately the same as that for bleeding gums. Although more cases were found among patients with blood ascorbic acid levels below 0.40 mg. per 100 cc., numerous cases were found among those with high levels.

Bleeding, hypertrophic gums suggesting scurvy were found in only 4 cases. One of these had an ascorbic acid level of 1.04 mg. per 100 cc. and showed excellent excretion when given a saturation test. The capillary-resistance test was negative, and since clinically there was only partial evidence, it was believed that the hypertrophic gums were on some basis other than vitamin C deficiency. Two cases had typical scorbutic gums and blood levels of ascorbic acid consistent with the diagnosis, but neither showed any decrease of capillary resistance. They were considered questionable cases of scurvy. The remaining case showed clinical signs of scurvy, and had chemical levels that supported the diagnosis. There was a rather low excretion of ascorbic acid on the saturation test, and a history of not having eaten citrous fruits for four or five months. Out of the 175 cases studied, this was the only one in which the diagnosis of scurvy was made.

CONCLUSIONS

If the clinic patients at the Cincinnati General Hospital are left to their own selection, they choose foods low in vitamin C. The cost of good vitamin C sources, such as citrous and fresh fruits, is higher than that for other carbohydrate sources, and in a clinic composed chiefly of charity pa-

nents, this factor is of considerable importance. An equally significant factor is the natural preference of this class of patients for foods like bread, dry beans and fat meat, in which the vitamin C content is low. It is impossible for these patients to increase food expenditure, but the matter of personal choice can be corrected by diet instruction. Diabetic patients who have come to the clinic regularly and have followed the diet instructions carefully have a more normal ascorbic acid level than new, uninstructed patients.

Although we believe that a normal intake of vitamin C is advantageous, we have discovered no concrete evidence that it has any effect on the state or severity of the diabetes. As many patients with a high level of ascorbic acid were taking insulin as those with a low level. Patients with adequate vitamin C nutrition had glycosuria and hyperglycemia just as frequently as those with inadequate nutrition, and low levels of ascorbic acid had no relation to the incidence of pyogenic processes.

Of considerable interest is the fact that almost half the patients observed had blood ascorbic acid levels under 0.40 mg. per 100 cc., yet only one case presented undisputed evidence of scurvy. One of two things must be at fault. Either there is a deficiency of some substance other than ascorbic acid in clinical scurvy, or we must revise the notion that the critical level for the appearance of scorbutic signs is 0.40 mg. per 100 cc. of ascorbic acid.

SUMMARY

One hundred diabetic patients who had been

under treatment and 25 untreated diabetic patients were studied with respect to vitamin C nutrition. All were clinic patients of low economic status. Two thirds of these patients had a blood ascorbic acid level under 0.80 mg. per 100 cc. Fifty non-diabetic patients were also studied, 90 per cent of whom had ascorbic acid below the prescurvy level (0.80 mg. per 100 cc.).

Dietary inadequacy, caused by lack of money and poor selection of foods, accounts for these low levels of ascorbic acid. The vitamin C status of diabetic patients is improved by diet instruction, even if the food expenditure is as low as \$2.10 a week.

Men were found to have lower than average levels of vitamin C, and patients with cataract had a higher level. Low-calorie diets, insulin administration, hyperglycemia and glycosuria had no apparent relation to blood ascorbic acid content. Only one case of scurvy was found, even though 81 out of 175 patients had blood ascorbic acid levels under 0.40 mg. per 100 cc.

POST-MORTEM EXAMINATION IN RURAL GENERAL PRACTICE*

WILLIAM F. PUTNAM, M.D.

LYME, NEW HAMPSHIRE

THIS report covers the results and significance of an attempt to establish as a routine procedure the performance of post-mortem examinations in a rural general practice, and is based on an analysis of the deaths occurring in the four years 1936 through 1939. Of 64 fatal cases, autopsies were performed on 34 (53 per cent); permission for autopsy was refused in 24 (38 per cent) and no permission was requested in 6 (9 per cent).

That the value of routine post-mortem examinations is little understood and appreciated by the lay public is well known. That the medical profession itself shares the apathy, if not the active antagonism, of laymen, must be inferred from the fact that the vast majority of deaths are not investigated by autopsy. In relatively few hospitals is the percentage of post-mortem examinations high enough so that the procedure can truthfully be called routine, and the number of examinations done on the bodies of those who have died outside hospitals is so small as to be negligible from a statistical standpoint.

The arguments that can be adduced for the routine performance of post-mortem examinations in hospitals apply with even greater force to the holding of such examinations in outside practice. Such examinations are the only conclusive means of ascertaining the cause of death, which is a matter of vital interest not only to all who try to draw conclusions from mortality statistics, but also to the family and physician interested in a particular patient. For the physician who has been taking care of a case, it is obviously more than interesting information, since the examination brings into sharp focus in proper relation, often for the first time, all the different stages and aspects of a disease. He is able to review the accuracy of his diagnostic procedures and the appropriateness and effectiveness of his therapy, thus making each fatal case highly instructive and very directly helpful in dealing with future similar cases. Furthermore, the knowledge that an autopsy will probably be held and the case reviewed by a department of pathology strongly encourages conducting a case in such a way that it will stand the light of analysis and discussion by others, and

will be a stimulus to the making of complete records and exact and accurate diagnoses.

The impartial knife of the pathologist is a certain antidote for conceit. Without autopsies, the natural tendency is to develop a blind confidence in one's habitual methods, which tends to be strengthened by the mere passage of time. The physician who is practicing by himself in a more or less isolated community, with no large hospital and few if any colleagues at hand, can more easily and quickly than any other arrive at a point where he feels an unjustifiable degree of self-satisfaction. Most of his diagnoses appear to be correct, or at least nothing occurs to cast serious doubt on them, most of his patients recover following his ministrations, and most of the deaths appear to be inevitable. One who does not take advantage of the opportunities that would be provided by post-mortem examinations on his own cases to recognize and remedy his deficiencies is in danger of ultimately becoming a liability to the community. With unjustified confidence in himself, he is in a position to do a great deal of harm through repetition of unrecognized mistakes.

Such an intensive clinicopathological review of one's cases provides a most effective way for a physician to broaden his knowledge of pathology and medicine. Especially one who is not connected with a teaching hospital has relatively little stimulus or opportunity for study. Only with difficulty and at considerable expense can he pursue definite postgraduate courses. Therefore it is especially important that he make use of such opportunities as are at hand, and certainly routine post-mortem examinations on one's own cases afford the country doctor a unique educational opportunity that is highly profitable and usually available.

This practice would do much to eliminate the double, or really multiple, standard of medical practice that now exists. Fundamentally, there is no reason why patients should not expect and receive just as scientific and satisfactory diagnosis and treatment from the rural general practitioner as from his colleague in the large hospital. They never will while the former continues to bury his mistakes unexamined. Nothing will raise the standard of rural practice of medicine so effectively as routine post-mortem examinations, and

*One of the two essays awarded the Pray and Burnham Prizes for 1940 by the trustees of the New Hampshire Medical Society.

incidentally, nothing will eliminate the bogey of state medicine so effectively as better standards of practice under the present system.

Besides the benefit to the individual physician or the small group that may be concerned with a particular case, each post-mortem examination adds at least a fragment to the general science of pathology, and there is always the possibility of adding something of great importance.

It is, of course, essential in private as in hospital practice to obtain from a responsible relative a valid, written permission for the performance of an autopsy, and obviously this is the first step in doing such examinations. This is easy in many cases, and possible in most if the physician making the request uses a proper approach. He must first have a sincere and strong belief in the value of the procedure, and secondly he must successfully convey to his hearer an appreciation of that point of view. A straightforward, confident approach, conveying the impression that it is routine and to be taken for granted, is all that is usually needed, and disposes at the outset of the argument that autopsies are not customary. The majority of objections encountered are illogical and invalid, and may be overcome by skillfully presenting the case. The commonest of all is the fear of disfiguring the body. This may usually be overcome by drawing an analogy to surgical incisions and pointing out that the exterior of the body is restored to approximately its natural condition so that there is nothing to prevent the usual type of funeral after an autopsy. Many people state that they do not want the body "cut up." A careful choice of words in describing the procedure, in addition to clearly setting forth the arguments in favor of it, will often dispel this prejudice. It is, however, essential to make sure that the person interviewed has an approximately accurate conception of the nature of the procedure, for if permission is granted under the impression that incisions are not involved, the autopsy might result in a most unfortunate misunderstanding. In some cases it is possible to mention the fact that natural decay soon defaces the body, and that an autopsy retards the process, rather than otherwise. One often encounters the attitude that the patient is dead and that the procedure will consequently do him no good. This should be countered by pointing out the opportunity to do good to others suffering from a similar malady, and usually it is possible to say that the patient himself would undoubtedly wish to do what he could to help others similarly afflicted. The possibility of direct and immediate benefit can be brought closely home in cases of possibly hereditary or

contagious disease, or when others in the family are already actually suffering from similar complaints. Occasionally people admit all this, but say that they are not interested. Although the discussion sometimes has to end at that point, it is usually possible, by pointing out in detail the ways in which post-mortem examinations benefit the community, to convince an intelligent person that he should be interested.

There always are at least a few cases in which permission cannot be obtained. An argument difficult to dispose of is the known objection of the patient. If he has previously exacted a definite promise that his body will not be examined, it is usually better to drop the matter. However, under extraordinary circumstances it may sometimes be pointed out that the patient made the request without having an opportunity to discuss the matter or to have explained to him its value under the particular circumstances existing at the time of his death, and occasionally relatives can be persuaded that the patient would probably have changed his mind if he had been in a position to appreciate all the factors involved. About the only other unanswerable argument is the absence of any argument at all. Occasionally one meets the stone-wall type of person who simply says, "I don't want it done," gives no reasons, agrees with all the arguments, and still flatly refuses. It is worth spending time to identify the type, but once it has been identified, further discussion is wasted effort.

It should go without saying that permission should not be bought or obtained by misrepresentation or by threats and intimidations. The harm done by such tactics would in the long run outweigh any possible advantage to be obtained from an individual autopsy.

Although obtaining permission is essentially the same problem in the home and in the hospital, certain circumstances peculiar to deaths occurring at home may make it a little more difficult. Some of these factors are relatively intangible, and are related to the apparently greater aura of authority that surrounds a physician in a hospital, where he seems to the patient and his family much more definitely in control of the situation than he does in the home, where the attitude often enough is that he is merely hired to come in at intervals for the specific purpose of leaving pills. Other more definite factors are related to the fact that a higher proportion of patients dying at home die of seemingly natural and inevitable causes, such as the degenerative changes of old age, which fail to arouse the interest and curiosity of the relatives. Occasionally, oftener in homes than in hospitals, it is impracticable to obtain or even request permission

because of the unavailability of the responsible party or for some similar reason. The responsible relative may have left with others instructions that were intended to cover all contingencies and may not be available for discussion of post-mortem examinations. In some localities it has become customary in chronic illnesses when death has long been expected to call the undertaker before the doctor, or even not to call the latter at all. It is of course illegal for the undertaker to proceed without a death certificate, and this practice

amination, including histologic study, can be made by an experienced physician with a well-equipped laboratory. Nevertheless, there is no reason why any physician could not do for himself autopsies that would be sufficiently complete to be of considerable value, and when the set-up is such that the services of a pathologist are not available, such an effort on the part of the general practitioner would be well worth while.

A number of special factors pertaining to outside autopsies must be borne in mind, regardless

TABLE 1. *Data on Cases on Which Post-Mortem Examinations Were Performed.*

CASE No	AGE	SEX	CLINICAL DIAGNOSIS*	PATHOLOGICAL DIAGNOSIS†
1	67 yr	M	Thyrototoxic heart disease	Thyrototoxic heart disease, perforated empyema of gall bladder
2	82 yr	M	Lobar pneumonia	Lobar pneumonia
3	8 days	M	Prematurity	Prematurity
4	75 yr	M	Coronary occlusion	Coronary occlusion
5	50 yr	M	Carcinoma of bladder	Carcinoma of bladder
6	83 yr	M	Cerebral hemorrhage	Myxedema
7	42 yr	M	Brain tumor	Glioma
8	7 wk	M	Bronchopneumonia	Otitis media, with lateral sinus thrombosis
9	2 days	M	Intracranial hemorrhage (birth injury)	Birth trauma
10	62 yr	F	Coronary occlusion	Pneumonia
11	75 yr	M	Arteriosclerosis (cerebral)	Hypertension
12	75 yr	M	Carcinoma of prostate	Carcinoma of prostate, lymphatic leukemia, diabetes mellitus ()
13	61 yr	M	Hypertensive heart disease	Hypertension, cardiac failure
14	70 yr	M	Cardiac decompensation, pulmonary edema	Aortic stenosis, cardiac decompensation
15	41 yr	M	Coronary occlusion	Ruptured aortic aneurysm
16	69 yr	M	Carcinoma of prostate	Carcinoma of prostate
17	73 yr	F	Hypertension, cerebral accident, bronchopneumonia	Infarct of cerebrum
18	84 yr	M	Dislocation of right knee, bronchopneumonia	Dislocation of knee, bronchopneumonia
19	81 yr	M	Coronary occlusion	Myocardial infarct (hemopericardium)
20	0	M	Birth trauma	Stillbirth, asphyxia
21	92 yr.	F	Carcinoma of colon	Carcinoma of cecum
22	66 yr.	F	Second degree burn, bronchopneumonia	Second degree burn, with infection (toxemia)
23	80 yr.	M	Diabetes mellitus, sepsis	Diabetes mellitus
24	0	F	Stillbirth	Stillbirth
25	67 yr.	F	Chronic arthritis, hyperthyroidism (?), lobar pneumonia	Cardiac failure, lobar pneumonia
26	81 yr.	F	Arteriosclerosis, diabetes mellitus	Diabetes mellitus
27	56 yr.	M	Coronary infarction, cardiac decompensation dietary deficiency	Cardiac hypertrophy, heart failure
28	78 yr	F	Cardiac decompensation, carcinoma of breast, carcinomatosis	Carcinomatosis, pulmonary thrombosis
29	54 yr.	M	Cerebral hemorrhage (right)	Thrombophlebitis, pulmonary embolism
30	86 yr.	M	Senility, pyelonephritis, bronchopneumonia	Cerebral arteriosclerosis, infarct of brain, carcinoma of prostate
31	73 yr.	F	Arteriosclerosis, cerebral hemorrhage, bronchopneumonia	Arteriosclerosis (cerebral), cerebral hemorrhage
32	81 yr.	F	Arteriosclerosis, starvation	Generalized arteriosclerosis
33	71 yr.	M	Cerebral hemorrhage	Fracture of skull (accidental)
34	1 day	M	Intracranial hemorrhage (birth injury), prematurity	Anomalies of heart, incomplete septa

*The diagnoses listed are those that were made in writing at the time of death, previous to the post-mortem examination. For the sake of brevity and to avoid confusion, only those conditions are listed that were assumed to be directly responsible for death.

†The diagnoses listed are expressed so as to give briefly the most significant information derived from the post mortem examination. In most cases the listing consists of the case title assigned to each case by the pathologist on the basis of the anatomic findings.

can be stopped by having a proper understanding with him. Although these factors will probably always operate to keep the percentage of non-hospital post-mortem examinations well below a hundred, it may be seen from this report that it is perfectly feasible to obtain a reasonably high percentage of permissions in a rural general practice.

The ideal arrangement calls for the co-operation of a pathologist or department of pathology of a medical school, in such a way that without expense to the patient a complete post-mortem ex-

of who does the examination. The co-operation of the undertakers serving the territory affected is important; if it is not willingly offered, it should be possible to convince undertakers that it is to their interest to co-operate, and that they are defeating their own aims by attempting to obstruct the performance of post-mortem examinations. In many cases, the undertaker's mortuary provides the most satisfactory place for the procedure, and that is far preferable to having an examination in a patient's home. The latter, however, is perfectly possible, and when necessary it can be done.

without making an undue amount of mess, on an ordinary bed and with but little special equipment. It should be performed expeditiously and quietly, and in such a way that no traces of the procedure remain.

In reviewing 34 cases on which post mortem examinations were done, with a view to discovering just how much practical value there was in doing the examinations, the cases fall into three groups (Table 1). The first, which may be picked out at a glance, includes the cases in which the clinical and pathological diagnoses were obviously different, and in which the autopsy revealed a more or less gross diagnostic error or omission. About 6 cases fall into this group, it would be hard to deny the value of the post mortem examination in such cases. Another 6 fall into the group in which the examination added no significant positive information, whereas the majority constitute an intermediate group, in which the findings were of considerable interest even though not unexpected or dramatic. It must not be inferred from such a classification of the cases that there is any intention of implying that autopsies are important only if they show unexpected findings, even those that reveal nothing that was not previously known are valuable in confirming the clinical findings, in filling in the details of the exact extent of the pathologic changes the nature of which was correctly suspected, and in demonstrating the absence of other findings.

These points will be illustrated by brief comments on typical cases.

CASE 1 This patient was an elderly man who had been operated on for hyperthyroidism. The diagnosis of the underlying condition was clear enough, as is usually true of patients who have undergone operation with pathological examination of operative specimens. However, there were many complications only indirectly related to the thyroid disease, and the examination was most informative with regard to these. The immediate cause of death, peritonitis due to a ruptured gall bladder, was not suspected previous to the autopsy.

CASE 2 The diagnosis of lobar pneumonia in this patient was confirmed, but the affected lobe was not the one expected. This was not of much importance in this particular case but the experience has encouraged more careful physical examinations in subsequent cases.

CASE 6 This patient was not observed before death, and the correct diagnosis, myxedema, might have been made if there had been an opportunity for clinical study. The facts are, however, that it was not remotely suspected on the basis of the available history, and that the implications of an unusual and instructive case would have been lost without an autopsy.

CASE 8 This case brought home with greater force than any other the practical value of post mortem examinations for this infant might not have died if a diagnosis of *Cytis media* had been made and treatment instituted

at the proper time. Without the autopsy the diagnosis would never have been suspected. This naturally has provided a strong incentive to make routine examinations of cadavers.

CASE 10 This case shows another glaring error, lobar pneumonia mistaken for coronary occlusion. The error should not have been made, but whether excusable or not, and whether prognostically important or not, the point here is that without the autopsy it would never have come to light.

CASE 14 There was no question that this man died of cardiac decompensation, but the autopsy provided important information about the anatomic changes in the heart, chiefly aortic stenosis, which it was well worth while to have the opportunity to correlate with the physical findings.

CASE 15 The attack of severe thoracic pain in this case was so suggestive of coronary occlusion that the diagnosis was made more or less unequivocally, but in retrospect, knowing that a ruptured aneurysm was found at autopsy, it seems as though the patient's age (41) and the known history of syphilis were leads that might have been followed up with a more careful examination, which, in turn, might have suggested the correct diagnosis. And of course this case, as well as Case 10, demonstrates the fallacy of making diagnoses of coronary occlusion without electrocardiograms.

CASE 19 This was a straightforward case of coronary occlusion, but the post mortem examination gave the interesting additional information that the terminal event was rupture of the heart, which could hardly have been diagnosed clinically.

CASE 21 The carcinoma of the cecum in this case was diagnosed approximately accurately before death, but it was not possible to be certain that the palpable mass was not some other kind of tumor.

CASE 28 This case was comparable to Case 1 in that the primary cause of death, carcinoma of the breast, was well understood, there were numerous complications, however, and the immediate cause of death, pulmonary embolism, was not suspected during life.

CASE 29 This case gave little opportunity for study before death; however, the patient was seen shortly after the onset of the terminal attack, and long enough before death to permit a reasonably careful examination. On the basis of this the incorrect diagnosis of cerebral hemorrhage was made, and the existence of thrombophlebitis with pulmonary embolism was not suspected.

CASE 30 In this case the incidental finding of unsuspected carcinoma of the prostate, of no clinical importance at the time of death and unrelated to the patient's main difficulties made the autopsy particularly interesting. This lesion would undoubtedly have assumed considerable importance if the patient had lived a number of months longer and this was a point of great interest to the family.

CASE 34 That this neonatal death was due to cardiac anomalies which incidentally, were very unusual and interesting was a considerable satisfaction from an obstetric point of view, for the death would certainly have been credited to birth injury if the autopsy had not been performed.

The cases on which no post mortem examination was made may be divided into groups sim-

ilar to those mentioned above. It may be seen at a glance that some of the diagnoses were vague and uncertain enough to be open to considerable question under any circumstances without an autopsy; in a few cases it was not even possible to make an intelligent guess. There is another small group in which the diagnosis was less doubtful, but still left room for question. In the majority

55	69 yr.	M	Carcinoma of prostate
56	88 yr.	M	Arteriosclerosis
57	89 yr.	F	Arteriosclerosis
58	75 yr.	F	Senility
59	75 yr.	M	Bronchial asthma
60	70 yr.	M	Arteriosclerosis
61	92 yr.	M	Senility, arteriosclerosis
62	75 yr.	F	Carcinoma of ileum, intestinal obstruction
63	76 yr.	M	Arteriosclerosis, diabetes mellitus
64	78 yr.	F	Hypertensive cardiovascular disease

of the cases there seemed little reason for questioning the clinical diagnosis. Again, however, there is no reason for supposing that a post-mortem examination would have been uninteresting or uninformative in even the most seemingly simple and clear-cut of these cases.

These points will be illustrated by brief comments on some of the cases.

CASE 37. This was an apparently normal newborn infant who lived 45 minutes. There was no clue in the mother's pregnancy or labor as to the cause of death, which remains unknown. Obviously an autopsy would have been helpful.

CASE 40. This exemplifies the type of case in which a presumably correct clinical diagnosis can easily be made. However, the clinical course and death attributed to cerebral thrombosis might, of course, have been due to any of a variety of intracranial lesions, and there is no way of knowing what other pathologic processes of importance may have been present.

CASE 41. There was no doubt about the diagnosis in this

case—carcinoma of the breast; the exact extent of the metastatic involvement, however, and the possibility of concomitant lesions remain unknown.

CASE 50. The diagnosis of carcinoma of the head of the pancreas in this case was not much better than a guess, made largely on the basis of severe and increasing jaundice, a palpable gall bladder, and death without other obvious explanation.

CASES 52, 54 and 58. These were all cases that had presented difficult diagnostic problems, none of which had ever been satisfactorily settled, in spite of fairly careful and prolonged study. Refusal to grant permission for autopsy, which would have been essential to obtaining any definite idea of the pathologic conditions present, was particularly disappointing.

It may be seen from the above tabulations and comments that among the cases autopsied there were enough in which the examination revealed important and unexpected findings to justify doing them all on that score alone. And, similarly, among those not autopsied there was a group in which a post-mortem examination was indispensable to the making of a definite diagnosis. But once more I should like to emphasize that important and necessary as autopsies are in making diagnoses in puzzling cases, they are also of great value in confirming and amplifying clinical diagnoses, whereas the most fundamental value of all is in the opportunity for clinicopathologic correlation. In going over these cases, I am convinced that there is no question whatever that the practice of doing fairly routine post-mortem examinations has been of definite and specific value to me, and that I am practicing better medicine today than I should have been able to do if these autopsies had not been done.

In view of these experiences and observations, I believe that some provision for encouraging the performance of autopsies in a truly routine manner, both in and out of hospitals, should occupy an important place in any program that seeks to elevate the standards of medical practice and improve the quality of medical care. In the midst of heated discussion of new methods of distributing and paying for medical care, one must not lose sight of the fact that a more fundamental matter is the quality of that care, and that poor medical care is not worth distributing, by any method or at any price.

The post-mortem examinations on which this report is based were done through the courtesy of the Department of Pathology, Dartmouth Medical School.

MEDICAL PROGRESS

SURGERY OF THE SYMPATHETIC NERVOUS SYSTEM

The Role of Vasospasm in Acute Lesions Involving Major Peripheral Vessels

REGINALD H. SMITHWICK, M.D.*

BOSTON

A NUMBER of interesting and valuable articles have appeared in recent literature concerning the role of vasospasm in acute lesions of the peripheral vascular tree. Dramatic and vastly improved results have followed timely intervention on sympathetic pathways to the vessels concerned in a number of conditions encountered in everyday practice. These reports concern the management of acute thrombophlebitides and of acute traumatic injuries of the peripheral vessels, such as gunshot wounds and lacerations, emboli and aneurysms.

ACUTE DEEP THROMBOPHLEBITIS

Thrombophlebitis has always been a very troublesome problem, particularly when it involves the large deep veins of the femoral and iliac regions. It may occur after or in association with operations, childbirth or any illness and, although rarely, may even be spontaneous. In its typical form it is sudden in onset, and may be associated with chills and fever. Very prominent manifestations are pain and swelling, the latter extending to the groin or even higher; the circumference of the leg may be increased. The extremity may be pale or cyanotic, and the surface temperature lower in the periphery. There is usually an elevation of the white cell count, and an increased sedimentation rate. Lesser degrees of this lesion are commoner than the typical phlegmasia alba dolens, and are the result of the involvement of smaller and more peripheral veins. This condition is to be differentiated from thrombophlebitis of superficial veins, in which swelling of the entire circumference of the leg is absent. It is also to be distinguished from phlebotrombosis, which, as the name implies, is to be considered the result of thrombosis without infection, fever, swelling, pain or leukocytosis—the usual signs and symptoms of deep thrombophlebitis.

The latter is of immediate interest not only because of the symptoms, but also because of the prolonged convalescence that it has necessitated in the past. Fortunately, death from emboli is rare, in contrast to the mortality resulting from phlebotrombosis. Deep thrombophlebitis also frequently

results in a varying degree of permanent swelling of the leg, which may be both unsightly and disabling. Added to this are difficulties with superficial varicose veins caused by the prolonged but rarely permanent deep venous occlusion. Trouble some ulceration related to destruction of valves in the communicating veins may also be a serious problem in later life. It is therefore of interest that so simple a measure as repeated blocking of the sympathetic nerve supply to the lower extremities with procaine hydrochloride should be followed by such dramatic changes that one may expect many of the immediate and late sequelae of deep thrombophlebitis to be largely eliminated. This form of treatment was first suggested by Leriche.¹ The results of such therapy, as well as its rationale, have been discussed in great detail in a number of communications by Ochsner and DeBakey.²⁻⁴

They picture the pathological physiology in the following manner. The deep venous channel is occluded by the thrombus. This serves as an irritable focus from which afferent impulses pass centrally by way of the perivenous sympathetic plexus, and result in reflex efferent vasomotor impulses to both peripheral arteries and veins. The resulting spasm of peripheral veins causes a marked increase in venous pressure, with augmentation of filtration pressure and relative anoxia of the capillary endothelium, both of which favor increased transudation of vascular fluid into perivascular tissues—in other words, edema. The arterial spasm results in a decrease in the magnitude of peripheral pulsations, which in turn makes for further stagnation of tissue fluids because arterial pulsation is essential to proper lymph flow. In their opinion, neither the mechanical blockage of the vein resulting from the thrombosis nor blockage of the lymphatics due to perivenous inflammation is of primary significance in the production of the clinical manifestations of thrombophlebitis.

To support this theory, Ochsner and DeBakey found that when the femoral vein of a dog was ligated, there resulted a marked diminution in the magnitude of arterial pulsation in the corresponding foot. If a chemical irritant (a 40 per cent

*Instructor in surgery, Harvard Medical School; assistant visiting surgeon, Massachusetts General Hospital.

solution of sodium salicylate) was placed within the lumen or in the perivascular tissue of an isolated segment of this vein, a further decrease in pulse volume resulted. However, interruption of nerve pathways by local infiltration of procaine hydrochloride around the site of the irritated segment or resection of the lumbar sympathetic ganglia and intervening trunk abolished or prevented this effect.

Clinically these authors note that in cases of thrombophlebitis there is also a reduction of peripheral arterial pulsation, and point to the fact that this may be so marked as to simulate arterial embolism. Decreased surface temperature and pallor are further evidences of arteriolar constriction. They found the venous pressure to be four or five times normal in 8 patients.

In the last year they have treated 15 patients with acute deep thrombophlebitis by paravertebral procaine hydrochloride block. In 2 cases, the process was bilateral; thus seventeen extremities were involved, only 1 being an arm. The condition followed operation in 7 cases, delivery in 4, infection in 3, and trauma in 1. Fever ranged from 99.6 to 104.8°F. There was swelling in all but one, with an increase in circumference of the extremity varying up to 9 cm. The length of time between the onset of the process and institution of treatment varied from one to twenty-eight days, and from one to six injections were required.

The following results were obtained. Relief of pain was prompt within half an hour of the first injection in many cases, and after the second or third in all. The fever disappeared in one to eight days—within forty-eight hours in approximately 50 per cent. The swelling completely disappeared in three to twelve days, the majority being relieved in ten. The length of hospital stay ranged from four to twelve days, with the exception of 2 patients, who remained for other reasons. The follow-up period varied from four to twelve months. No recurrence of edema was noted, and no other postphlebotic manifestations appeared.

For the lower extremities, paravertebral novocain block is done in either the lateral or the prone position. Four needles are inserted vertically opposite the upper borders of the upper four lumbar spinous processes, 5 cm. lateral to the mid-line. After making contact with the corresponding transverse processes, the needles are inclined slightly inward and inserted 5 cm. deeper. Five cubic centimeters of 1 per cent procaine hydrochloride is injected through each needle.

To denervate the upper extremity, Ochsner and DeBakey recommend the anterior approach, inserting one needle just above and 1 cm. medial to the center of the upper border of the clavicle, horizontal and at an angle of 45° with the mid-line,

thus contacting the side of the body of the seventh cervical vertebra or the ligament between that and the first dorsal vertebra. Ten cubic centimeters of 1 per cent novocain are injected. Caution must be taken to prove by aspiration that the needle is not in a blood vessel, in the spinal canal or within the pleural cavity. Similar precautions should, of course, be observed when blocking the lumbar trunk.

They believe that the injections should be repeated every forty-eight hours as long as the fever persists. They also emphasize that treatment should be instituted promptly. They prefer repeated novocain block to alcohol injection, since maximal vasodilation follows each injection, whereas if the sympathetic ganglia and chain are destroyed by either surgical removal or alcohol, the maximal response occurs for a short period and cannot be repeated.

Although some might disagree with the dismissal of mechanical blockage of a thrombosed vein or perivenous lymphatic blockage as playing an unimportant role in the production of the manifestations of acute thrombophlebitis, and although others might disagree with the technic of paravertebral novocain block, few would fail to agree that the clinical results of this form of treatment are good. If late perivenous fibrosis and lymphatic obstruction are prevented,—and there seems every reason to believe that they will be,—there should be no recurrence of the edema. It seems possible also that inhibition of venous spasm may shorten the period of complete venous obstruction and may result in a more rapid recanalization of the involved segment. This should lessen the incidence of superficial varices, and of ulceration due to incompetence of communicating veins.

ACUTE LESIONS OF LARGE PERIPHERAL ARTERIES

Acute interference with the main arterial supply to an extremity may result disastrously for the limb and even the patient. This is apter to happen in the leg than in the arm. Survival of the extremity depends to a large extent on the state of the collateral circulation, the nature and location of the lesion, the age of the patient, the presence or absence of organic vascular disease or serious disease elsewhere in the body, and the promptness with which treatment is instituted. Too frequently, however, extremities have had to be sacrificed in spite of all efforts to save them, even when conditions were most favorable. Recent reports emphasize that many of these extremities can be saved if the importance of associated vasospasm is appreciated and promptly eliminated.

Whether the acute arterial deficiency is due to

a gunshot wound, to a traumatic laceration, to an embolus, to surgical ligation of a normal artery, to acute interruption of main-vessel blood flow in the process of obliterating, ligating or excising a peripheral aneurysm, or to spontaneous rupture or thrombosis of the latter, the effect on the collateral circulation, even when adequate beforehand and not the site of organic disease, is extremely important. In all these conditions, the main-vessel flow is effectively blocked, and may be still further occluded by both distal and proximal thrombosis. The only possible source of supply to points distal to the obstruction or site of injury is collateral circulation.

When a large peripheral artery is suddenly occluded, a rather characteristic group of signs and symptoms is noted, commencing with pain and cessation of peripheral pulsation, and followed by various color changes in the skin—usually a mottled combination of pallor and cyanosis. The limb distal to the obstruction becomes anesthetic and cold, and voluntary motion diminishes or disappears. If this condition is allowed to persist for more than a few hours, irreversible changes usually take place, and the extremity becomes gangrenous in a very high percentage of cases.

These changes are undoubtedly similar to those described by Carcassone and Haimovici (De Bakey⁶). The former introduced a balloon into the femoral artery of a dog and found that when the blood flow was quickly and completely obstructed by inflation a characteristic response occurred. This consisted of spasm of the main artery distal to the obstruction, which also affected arterioles and even capillaries. This vasospasm involved the collateral arteries in the neighborhood of the obstruction and at a distance as well. If, however, the occlusion was gradual or incomplete, this diffuse vasospastic response was not initiated.

That intense spasm of the main artery always exists distal to an occluding embolus and presumably involves the collaterals is well known, and has been noted many times at operation. That perivascular trauma may result in intense segmented arterial spasm simulating occlusion is also appreciated.

The importance of this mechanism has been recently discussed in great detail by Gage and Ochsner,⁶ who report a number of successful results following sudden occlusion of major peripheral vessels. They demonstrate that in man as in animals, this diffuse vasospasm can be abolished by excision or temporary destruction (by alcohol) of the sympathetic nerve supply to the extremity. When this is done in conjunction with surgical procedures such as ligation, division or obliteration of the major arteries, the outcome has been uniformly successful even when inadequate col-

lateral circulation was known to have existed previously. The technic for sympathetic block is the same as that described in connection with the treatment of acute deep thrombophlebitis. The needles are left in place for twenty to thirty minutes. When a rise in surface temperature and inhibition of sweating demonstrate the block to be successful, 5 cc. of 95 per cent alcohol is injected through each needle.

Their results are of interest and follow:

We have used the physiologic method, i.e., sympathetic block, of increasing the collateral circulation as a preliminary procedure to the ligation of major peripheral arteries in 10 cases. In all but 2 of these cases the collateral circulation was found to be inadequate by the Matas compressor test. In the other 2 cases, one of which was an aneurysm of the common iliac and the other a stab wound of the common femoral, the test could not be applied. Of these 10 cases, 1 was a mycotic aneurysm of the right common iliac artery. Following sympathetic block and ligation of the common iliac at its origin, there was no change in color and no decrease in temperature of the corresponding extremity. There were 2 cases of arterial aneurysm of the femoral artery and 3 cases of popliteal aneurysm that were cured by obliterative endoarteriomorrhaphy. Three of the cases consisted of arteriovenous aneurysm, 2 of which were femoral and 1 was popliteal. These were treated by quadruple ligation. There was 1 case of stab wound of the common femoral, which required ligation. In none of these cases of ligation of the major peripheral arteries treated by preliminary sympathetic block was there any evidence of ischemia or deficiency of the peripheral circulation. We have also used sympathetic block in 4 cases of embolus of the femoral artery. In 1 case the embolus was removed after sympathetic block. The other 3 cases were not operated upon. In all these cases the classic clinical manifestations of arterial embolism were present. Following novocain block of the lumbar sympathetic ganglia and chain on the affected side, there was a loss of numbness and a return to normal of color and temperature to the extremity. In peripheral arterial embolism there is not only a high incidence of ischemic gangrene but a high mortality, the gangrene increasing the mortality. Therefore, we believe that sympathetic block will not only materially decrease the incidence of ischemic gangrene but will also lower the immediate mortality.

By contrast with the results in similar cases in the past, these are, to say the least, impressive. Ligation of the main vein at the same level as the artery has lowered somewhat the incidence of ischemic gangrene. It was not done in these cases, and the results are far better than one could expect in similar cases treated by simultaneous ligation of major arteries and veins. Peripheral aneurysms have been successfully treated with a rather low incidence of gangrene if operation was deferred until the collateral circulation was found to be adequate. Use of the Matas compressor has been most helpful in this connection. However, when rupture, or thrombosis, or rapid increase in size of the aneurysm had taken

place, forcing surgical intervention before the collateral circulation was adequate, the incidence of gangrene was high. Furthermore, a significant percentage of extremities were lost after removal or obliteration of aneurysms, even if the collateral circulation was known to be adequate beforehand. The saving of four consecutive extremities after embolic occlusion of the common femoral artery without removal of the embolus in three is noteworthy. The incidence of gangrene in the past, whether or not the embolus was removed, has been approximately 70 per cent.

The importance of these results cannot be overemphasized. The sympathetic supply should be interrupted by one method or another either at the time of or before operations that will result in sudden occlusion of major vessels. When spontaneous occlusion has occurred, as from embolism, laceration or thrombosis, the time factor is extremely important. Treatment, with or without embolectomy or other vascular surgery, should be instituted immediately—within an hour or two if possible, certainly within six hours. Every hour lost is important, because if diffuse vascular thrombosis is allowed to take place, the extremity is doomed. Thrombosis is due to stagnation of circulation and damage to the endothelium of the vessel wall resulting from anoxia. After this has occurred, release of vasospasm will no longer be followed by restoration of adequate blood flow.

The question of the best method of interrupting vasomotor pathways to the extremities has been raised by Veal,⁷ who advocates surgical interruption of sympathetic pathways at the time of repair of aneurysms of the extremities. He prefers this to chemical block (by alcohol) because it is more permanent, and better late results are to be expected. He reports 3 cases treated by combined sympathectomy and repair of aneurysms by multiple ligation or endoaneurysmorrhaphy. The arteries involved were the brachial, the femoral and the popliteal. The aneurysm of the latter was spontaneous; the others resulted from a laceration and a gunshot wound. In all, a rapid development of collateral circulation after operation was demonstrated by arteriography.

Alcohol injection appears to be the method of choice in treating patients in shock or the average case of embolic occlusion; the latter is nearly always associated with a serious cardiac lesion, so that the possibility of multiple episodes should be kept in mind.

Denervation of the lower extremity by alcohol injection is less difficult and less dangerous, and is followed by a much lower incidence of peripheral neuritis, than denervation of the upper extremity. Surgical excision of the appropriate portion of the lumbar sympathetic trunk is likewise

easier than the operation necessary to denervate the arm. The technic of these operations has recently been described in detail.⁸

It seems wise to denervate the lower extremity surgically when one is able to choose between the two methods, particularly if a prolonged and permanent effect is desired.

Paravertebral alcohol injection of the sympathetic supply to the upper extremity is difficult to perform and somewhat dangerous, and is followed by a high incidence of brachial and intercostal neuritis. It should be used principally as an emergency technic. Surgical denervation by preganglionic section seems the method of choice in treating other lesions. Much the same opinion about the advantages of surgical excision over alcohol has recently been expressed by Flothow⁹ after years of experience with both methods; he had previously favored alcohol.

Prompt intervention designed to interrupt vasomotor pathways to the extremities by one method or another is indicated in the treatment of acute occlusion of major peripheral vessels. This abolishes vasospasm and will lower the incidence of gangrene, which it has precipitated too frequently in the past.

If extensive thrombosis occurs, gangrene will follow. It seems appropriate to call attention to the use of heparin to prevent thrombosis. Murray¹⁰ recently published a summary of early experiences with this substance, and the indications are that it will prove to be an extremely valuable adjunct in the management of vascular lesions, particularly in reconstructive operations on major arteries after embolectomy, as well as in the treatment of thrombophlebitis. Elimination of vasospasm, combined with intravenous administration of heparin to prevent thrombosis, should go far toward reducing the high incidence of ischemic gangrene following the sudden occlusion of major peripheral arteries.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITALANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD G. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27081

PRESENTATION OF CASE

First Admission. A fifty-eight-year-old Italian laborer entered the hospital complaining of progressive enlargement of the abdomen of three weeks' duration.

The patient was seen for the first time four years before admission, when he entered the hospital complaining of sharp, postprandial, epigastric pain relieved by food and alkalis of four months' duration. The day before admission, hematemesis occurred. X-ray studies and gastroscopy revealed a macroscopically benign 1-cm. ulcer on the lesser curvature of the stomach with an associated gastritis; the esophagus appeared normal. In addition the patient was found to have a hypochromic anemia, acute gonorrheal urethritis and a positive blood Hinton test. A Takata-Ara test was positive, and bromsulfalein tests varied from 5 to 30 per cent retention. He was discharged six weeks later on a dietary regime, and at that time x-ray examinations showed a satisfactory reduction in the size of the ulcer.

Second Admission (ten months later). In the interval, the epigastric pain had gradually increased with the onset of anorexia and frequent gastrointestinal upsets; one week before admission the patient had vomited a grossly blood-free material. He had lost 15 pounds. The additional and abnormal findings were as follows: There was tenderness over the entire epigastrium, and the liver was palpable two fingerbreadths below the costal margin. Examination of the heart and lungs was negative, the peripheral arteries were tortuous, and the blood pressure was 180 systolic, 80 diastolic. X-ray films showed slight enlargement of the heart in the region of the left ventricle, with a tortuous aorta and calcification in the aortic knob. The stools were guaiac negative, the blood Hinton test positive; anemia was no longer evident. On the second hospital day, a partial gastrectomy and Polya anastomosis were performed. Pathological examination showed a benign gastric ulcer on the lesser curvature. Post-operative x-ray studies showed a poorly functioning anastomosis, with almost complete retention of the barium; the anastomosis was therefore ex-

ploded ten days later. It was found that the opening through the transverse mesocolon had slipped down over the afferent and efferent loops of the Polya anastomosis, with consequent kinking of the jejunum. This was repaired with satisfactory results, and the patient was discharged six weeks after admission, following an essentially uneventful convalescence.

Final Admission (three years later). In the previous three years the patient had been well except for a slight feeling of weakness; his gastrointestinal symptoms were relieved completely, and he had gained 17 pounds. Three weeks before admission, he noticed a progressive, painless enlargement of his abdomen. Soon this was followed by swelling of the ankles, scrotum and penis, worse in the evening, absent in the morning. Occasionally there was a dull pain in the subcostal region on both sides, and he complained of dyspnea on exertion and a chronic cough with white sputum but no hemoptysis. Although his appetite remained good, it was appeased by two slices of bread and a small amount of vegetables. His urine became scant and dark; there was no change in the character of the stools. No history of alcoholic overindulgence was obtainable.

The past and family histories were irrelevant.

On examination the patient was well developed and well nourished, but in no apparent distress; the skin and scleras were slightly icteric. Examination of the heart showed slight enlargement to the left, with a harsh systolic murmur over the precordium, heard maximally at the apex. Examination of the chest revealed dullness to percussion, diminished tactile fremitus and voice sounds over the right back below the eighth rib, up to the third rib in the axilla and below this level anteriorly. The abdomen was markedly distended, dome shaped, tense and tympanitic to the flanks; shifting dullness was present. Liver dullness was present to a point 5 cm. below the costal margin. There was pitting edema of the legs, sacrum, scrotum and penis. Rectal examination was negative. Examination of the nervous system was negative.

The temperature was 101°F., the pulse 85, and the respirations 20.

Examination of the urine showed a ++ test for albumin and a + to ++ test for bile; the urobilinogen was positive up to a dilution of 1:80. Examination of the blood showed a red-cell count of 4,000,000 with a hemoglobin of 75 per cent, and a white-cell count of 8400 with 73 per cent polymorphonuclears. The serum van den Bergh was 4.5 mg. per 100 cc., biphasic, a bromsulfalein test showed 55 per cent retention, and a formol-gel

test was positive. The nonprotein nitrogen of the blood serum was 22 mg. per 100 cc., the total protein 6.97 gm., with 2.28 gm. albumin and 4.69 gm. globulin (ratio 0.49). The prothrombin time was normal; a hematocrit reading was 42.1 per cent. Blood Hinton and Wassermann reactions were positive. The sputum was essentially negative, and no tubercle bacilli could be found in a smear. Examination of the stools was negative.

X-ray films of the chest showed the diaphragm to be unusually high, with atelectasis at the right base. There was a diffuse mottled density involving the greater portion of the left upper lobe, with a suggestion of a cavity overlying the first rib. The heart was normal, the aorta calcified. There were no enlarged lymph nodes, and no metastases were seen in the bones.

A gastrointestinal series showed a wide esophagus with extensive curling (adhesions), but definite varices could not be demonstrated. The abdomen was huge and dense. The lower two thirds of the stomach had been resected, and there was good function of the anastomosis and no evidence of disease in the stomach. Marked degenerative changes were present in the lumbar spine. There was no evidence of splenic enlargement.

The patient was placed on a high-calorie, high-vitamin diet and intravenous 25 per cent glucose, and an attempt was made to improve kidney excretion. An abdominal paracentesis yielded 3500 cc. of clear straw-colored fluid with a specific gravity of 1.012; this procedure was repeated on the fifth hospital day, when 5000 cc. of fluid was obtained. The serum van den Bergh was then 5.5 mg. per 100 cc., the white-cell count 11,200. Fluid gradually accumulated at the lung bases, especially on the left, and the patient became drowsy and coughed a great deal. An x-ray film of the chest three weeks after admission showed a homogeneous density on the left side, with an increased, more localized density in the infraclavicular area. This localized area had markedly increased since the previous examination. The right side was unchanged. The sputum grew a few colonies of beta hemolytic streptococci, and a blood culture was negative; the temperature was 102°F., and the white-cell count 19,000. Finally, fluid became still more pronounced at the lung bases, but the ascites seemed to diminish. The patient's breathing became labored, his color was ashen and icteric, and edema of the hands developed. Death occurred one month after admission. Throughout hospitalization, the temperature spiked to 102°F., gradually tending to remain elevated until the last four days, when it dropped below normal.

DIFFERENTIAL DIAGNOSIS

DR. THOMAS V. URMY: May we see the x-ray films?

DR. AUBREY O. HAMPTON: On first inspection of these films, I am inclined to disagree with the report. The esophagus does not look normal to me. I should hesitate to rule out varices. True, the patient had curling or adhesions to confuse the picture. I should certainly suspect that he had varices.

DR. URMY: Am I correct in believing that the X-ray Department attaches no significance to curling?

DR. HAMPTON: It does not mean anything. It just makes the examination more difficult in a case in which one suspects varices.

I suppose you are most interested in the chest. The films were taken twenty-one days apart. I do not believe that the heart is enlarged. The aorta shows calcification without dilatation. There was extreme arteriosclerosis.

DR. URMY: Is the dome of the diaphragm nodular or irregular?

DR. HAMPTON: You cannot see it quite well enough to be sure, but I do not believe it is either nodular or irregular. The liver does not look large.

I do not know what this is in the left upper lobe. There is rapidly progressive consolidation, and it appears that there are cavities without a shift in the mediastinum. It does not look like tuberculosis, but rather like some acute infection. At this time the patient had pleural disease also, and there is probably a diffuse effusion over the left lung.

DR. URMY: The cavities have increased tremendously.

DR. HAMPTON: Yes, unless they tapped his chest. The cavities in his chest look more like those due to gangrene than those produced by abscess or tuberculosis.

DR. URMY: For the sake of simplicity I think we can eliminate a certain amount of the history. The first four years seem mainly concerned with a condition that does not play any part in the final admission. The patient first came in with a hematemesis and a story consistent with ulcer. Although such a lesion was demonstrated both by x-ray examination and gastroscopy, there was also some gastritis, which might have been the source of the bleeding. In addition there was a suggestion of liver disease because of a positive Takata-Ara test and a sometimes abnormal bromsulfalein test. However, the correctness of the diagnosis of ulcer as the source of the hemorrhage and the cause of the symptoms seems to have been

borne out by the subsequent course, since the gastric resection apparently relieved all symptoms, except for slight weakness, for a period of three years. In the light of the final admission, we are mainly interested in the early suggestion of hepatic disease. The liver was probably not enlarged at the early admission. I also view as significant the statement that the patient remained weak during the three years between his second and third admissions; this is consistent with chronic hepatic disease. At the first admission a probable diagnosis of syphilis was also made. The positive Hinton test was confirmed at the third admission.

When we reach the final admission, we should like to know more about the patient's syphilis, especially whether he had had treatment during the interval and, if so, what sort of drugs had been used, because as we go along we wonder whether arsenic poisoning might have entered the picture. We also wonder whether the patient had had sufficient treatment to eliminate active syphilitic disease of the liver.

On the third admission the patient showed ascites and edema. The ascites had come first, which is suggestive of portal obstruction in addition to a more generalized cause of edema. Therefore in view of the knowledge of probable liver disease it seems logical to try first to connect the ascites and edema with a diseased liver. Liver disease is borne out by various observations at the last admission. The patient was icteric. The size of the liver was uncertain. On physical examination it was found enlarged to percussion, but this finding is of dubious value because the abdomen was markedly distended. The liver edge was evidently not actually felt, nor do we know whether it was palpated later after abdominal tap. The x-ray plates seem to refute the suggestion that there was enlargement. The spleen also was not enlarged, according to the x-ray films. Various laboratory tests pointed to hepatic disease. The increased urobilinogen in the urine could be due to increased blood destruction, but with a biphasic van den Bergh, not an indirect reaction, I think we can assume the cause to be impaired hepatic function. The albumin-globulin ratio was quite striking. A marked drop in albumin with a rise in globulin is consistent with hepatic disease; in fact, in the absence of appreciable loss of albumin in the urine, it is very strong evidence of severe liver damage. The bromsulfalein, as well as the formol-gel, test is also confirmatory.

We might consider cardiac edema because the patient complained of dyspnea and is reported to have had a loud cardiac murmur that was not noted at the first admission. He also had cough.

On the other hand, the heart was probably not enlarged, and the murmur not typical enough to permit a diagnosis of valvular disease. The lack of enlargement alone is enough to make one think that the heart was not impaired. In addition, heart disease could not, of course, explain all the physical and laboratory findings. I should not seriously consider either nephrosis or nephritis as the cause of the edema. We might mention infection in the peritoneum as a possible cause of the ascites, but it would not explain much more of the clinical picture. When the abdomen was tapped, the fluid had a specific gravity of 1.012, which is certainly on the transudate side, although a little higher than most transudates. There is no mention of cellular elements. However, I think we can be sure that the fluid was a transudate and not an exudate.

Another important part of the picture is the pulmonary disease, which Dr. Hampton has not been able to classify, and which I am quite certain I cannot. According to the history, the patient had had a chronic cough. On the other hand, x-ray studies within three years had not shown any pulmonary disease. We can say that the condition was progressive and probably of rather recent origin. Tuberculosis is not ruled out by one sputum examination. We can think of pneumonia, and perhaps that is the most tenable diagnosis, in spite of the fact that no pneumococci were found in the sputum. That is as far as I can go. There was infection in the lung, and there was also pleural fluid, which I should judge to have been part of the general fluid disturbance, although it is curious that the collection was on the left side instead of the right, where we should expect it to have been more marked.

The patient ran a higher temperature than most people with cirrhosis do, even in the terminal stage. The chest condition was, I think, the major cause of the fever. This assumption is borne out by the white-cell count, which rose instead of declining, as it does in liver failure. Furthermore, I think we can assume that the rapid progress of hepatic insufficiency was accelerated by the chest infection and that the patient's death was due not exclusively to liver failure but also to general toxemia from infection. Another possible explanation of the increased fever is cancer; and cancer does, of course, sometimes develop in a previously cirrhotic liver. One other explanation of the higher fever than that usually seen in cirrhosis is gumma of the liver. We might seriously consider gumma if we knew that the patient had not had treatment for syphilis.

In many cases of portal cirrhosis we find posi-

tive blood Hinton tests and wonder how much of a part syphilis is playing. At the postmortem, scarring typical of syphilitic cirrhosis is not found as a rule. I think, therefore, that on the law of averages this case will show a nonsyphilitic cirrhosis. The history of alcohol is a bit difficult to interpret. The history taker believed that the patient had not overindulged in alcohol, but does not tell how much he consumed. However, the patient was an Italian, and we have seen Italians in this hospital with portal cirrhosis who have only drunk wine. It is possible to interpret the statement in the history to the effect that he had been a wine drinker, but not a drinker of hard liquor. Antisyphilitic treatment—arsenic—I have mentioned as a possible factor in precipitating hepatic failure.

In summary, then, I think that the patient had a portal cirrhosis of the liver; he had had signs of the disease for at least four years before the final admission, but his liver had functioned fairly well until a short time before the last admission. His very rapidly downhill course at the end was, I believe, due to a new factor in the picture: a fairly acute pulmonary infection, apparently nontuberculous. He evidently also had syphilis, which may have played a part in producing the liver disease. There was, in addition, hypertension of a mild degree, but probably no important cardiac lesion. I do not believe that the previous ulcer and resection played any part in the final picture.

CLINICAL DIAGNOSES

Cirrhosis of liver, toxic.
Varices of esophagus?
Tuberculosis of lung, left upper lobe?
Bronchopneumonia, terminal.
Hydrothorax, left.

DR. URMY'S DIAGNOSES

Portal cirrhosis of the liver.
Syphilis.
Hypertension.
Pneumonia?

ANATOMIC DIAGNOSES

Alcoholic cirrhosis of liver.
Esophageal varices.
Jaundice.
Ascites.
Peripheral edema.
Pulmonary tuberculosis, with cavitation (left upper lobe).
Empyema, left.
Syphilitic aortitis.

Operative wounds: Polya resection of stomach, old; paracentesis, old and recent; peritoneoscopic incision, recent.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The post-mortem examination showed, as Dr. Urmey predicted, that the chief cause of death was cirrhosis of the liver. The liver was fairly small, weighed only a little over 1000 gm., and was definitely atrophic, very finely and diffusely granular and extremely tough when one attempted to cut it. On microscopic examination it showed hyaline degeneration, which we ordinarily associate with alcoholic cirrhosis and with alcoholic cirrhosis produced by drinking something stronger than Italian red wine. The Italian patients, as we see them in this hospital, show a disproportionately high incidence of cirrhosis, but do not show this very finely granular type of liver and do not show hyaline degeneration. This liver would have passed for an Irishman's. There were esophageal varices; they were not large, however. The spleen was quite small, weighing only 250 gm. The left pleural cavity contained over 2 liters of cloudy fluid, and the left lung showed numerous cavities surrounded by miliary tubercles and areas of caseous pneumonia. The patient did have morphologic evidence of syphilis. The ascending aorta was definitely dilated, showed atheroma greater than that of the descending aorta, a good deal of longitudinal wrinkling and a few stellate scars. The sinuses of Valsalva were markedly dilated, and they were so capacious that one could very easily have put a large marble into each sinus. The mouths of the coronary arteries were constricted.

DR. HAMPTON: Do you think that syphilis had anything to do with the extensive calcification in the aorta?

DR. MALLORY: It may have. I think there is no question that syphilis of the aorta predisposes to particularly severe atheroma of the segment involved by the syphilis. There was very slight separation of one of the aortic commissures, but not enough to produce free regurgitation.

CASE 27082

PRESENTATION OF CASE

A sixty-nine-year-old woman entered the hospital complaining of upper abdominal pain.

For years the patient had been troubled with indigestion and a feeling of heaviness in the left upper quadrant of her abdomen, associated with gaseous eructations and belching of sour, burn-

ing material, soda relieved these symptoms. For the previous month she had noticed a "dark-brown" taste in her mouth each morning, and on one occasion three weeks before admission she thought that her skin was yellow. After a meal, six days before admission, the patient was seized with a severe aching pain in the epigastric and periumbilical regions. Nausea and vomiting soon followed, and although the pain became steadily worse, it was relieved to some extent by lying down; the vomitus was dark brown and bitter. She remained in bed until the time of admission; pain was present most of the time, but fluctuated in its severity. Vomiting continued, and her abdomen became slightly distended.

The patient had been in the habit of taking salt laxatives two or three times a week for some time. During the month before entry she had found it necessary to increase the dosage, and the day before and again on the day after the onset of abdominal pain she took still larger doses. Evacuation was copious on both occasions. However, she had had no bowel movements during the four days before admission and had eaten nothing. Furthermore, the patient stated that she had always consumed large quantities of water, and that for the previous six months she had urinated on an average of three times during the night and four times during the day.

The patient had had diphtheria and the usual childhood diseases. Ten years before admission she had had a radical mastectomy for cancer, and seven years before entry an appendectomy, followed shortly afterward by the repair of an incisional hernia. Five sisters and three brothers were said to have died of either tuberculosis or "inflammation of the bowel."

On examination the patient was well developed, obese and apparently ill. A healed mastectomy incision was present in the right chest. Examination of the heart was negative, the blood pressure was 150 systolic, 100 diastolic. Fine crackling rales were heard at the left lung base. The abdomen was distended and tympanitic, with generalized tenderness, high pitched peristaltic sounds were heard best over the umbilicus. The reflexes were normal.

The temperature was normal, the pulse 110, and the respirations 22.

Examination of the urine showed a ++ test for albumin and +++ test for sugar. Examination of the blood showed a red cell count of 5,890,000 with a hemoglobin of 18.9 gm (photoelectric cell technic), and a white-cell count of 13,600, of which 84 per cent were polymorphonuclears. The non-protein nitrogen of the blood serum was 35 mg

per 100 cc, the chlorides 100.1 milliequiv per liter, and the blood sugar 294 mg per 100 cc. A blood Hinton test was negative. The stools were brown and guaiac negative on two examinations, the vomitus was also guaiac negative.

A plain x-ray film of the abdomen showed a number of gas filled, slightly dilated loops of small intestine. The one in the mid abdomen appeared to be ileum, the others suggested jejunum. There was a small quantity of gas in the stomach, but none was seen in the colon.

Attempts to insert a Miller-Abbott tube resulted in failure, for it would not pass the pylorus. Very little drained from the stomach, and abdominal distention and tenderness increased. The patient was given insulin and glucose, the fasting blood sugar ranging between 180 and 295 mg per 100 cc. An x-ray film of the abdomen two days after admission showed that the loops of small bowel formed a stepladder pattern in the left side of the abdomen, the Miller-Abbott tube still lay in the stomach. The next day, moisture developed in the right lung base, without signs of consolidation, the white cell count was 10,400, the temperature 99.7°F, the pulse 100. On the sixth hospital day an exploratory laparotomy was performed under spinal anesthesia through an old midline hernia repair scar. There were no omental adhesions at the site of the previous operation, and no free fluid. Uniformly dilated small bowel could be observed down to the region of the ileocecal valve, and no areas of collapsed bowel were found. The cecum was pulled into the right upper quadrant by an omental attachment, which was firm and sclerotic, and beyond this it was obviously edematous, as the result of a recent inflammatory process; this was freed up. The cecum was markedly dilated, as was the transverse colon to the splenic flexure, the descending colon was approximately one fourth the diameter of the transverse colon. Nothing suggestive of cancer could be found in the region of the splenic flexure. The balance of the colon down to the rectum was explored, but nothing could be found to explain the patient's symptoms. There were no areas of fat necrosis, and although there was some scarring of the undersurface of the liver and around the duodenal cap, no mass could be outlined in the gall bladder or head of the pancreas. No explanation could be offered for the failure of the Miller-Abbott tube to pass into the pylorus. The pelvis and its organs appeared normal. Because of the symptoms of intestinal obstruction, the dilated cecum and the uniformly dilated bowel down to the ileocecal valve, a cecostomy was performed through a McBurney incision.

DIFFERENTIAL DIAGNOSIS

DR. CLAUDE E. WELCH: This is a case in which I believe it is important to review the past history to look for leads that might explain the events to follow. The pains in the left upper quadrant of the abdomen and the gas and belching, relieved by soda, both point to either the stomach—possibly an ulcer, possibly gastritis, possibly diaphragmatic hernia—or the gall bladder. The “dark-brown” taste means nothing to me. The fact that she thought her skin was yellow may or may not be of significance. If it were accepted as true, it would give some indication that the biliary system was at fault.

From the history, there are two or three other organs that we can identify as possible causes of trouble. From the story of increasing constipation, of course, we wonder immediately about the colon. Then the suggestion of diabetes brings the pancreas into mind. With an operation for carcinoma of the breast and an appendectomy followed by adhesions, we have two other causes for intra-abdominal difficulty.

Her present illness of six days' duration is important in two respects. The pain began in the epigastric region and was followed very shortly by nausea and vomiting, and I should infer from the history that the vomiting was almost continuous from that time and that the pain remained in the same location. That will be very important when we discuss the site of her difficulty a little later.

The physical examination gave evidence of ileus of some type, almost certainly dynamic, in view of the high-pitched peristaltic sounds. The white-cell count is of a great deal of interest, because that, combined with a normal temperature, more or less eliminates an inflammatory lesion and makes us think much more of mechanical obstruction. The blood chemical findings are not abnormal except for the evidence of diabetes.

The only thing not mentioned on physical examination is the rectal examination, which I assume we may regard as negative.

DR. AUBREY O. HAMPTON: This patient had almost daily x-ray examinations, beginning on the third of the month and extending to the seventh. During that time she had dilated loops of small bowel that varied somewhat in size, and occasionally gas was visible in the colon. The frequent examinations were directed mostly at determining the progress of the Miller-Abbott tube. The tube would not go through the pyloric valve, no matter what we did. Multiple fluoroscopies and all sorts of manipulations were of no value. Finally she was given some barium to see why the tip of the

tube would not go through the pylorus. Only a swallow was given, and we found a definite abnormality in the duodenum. This is the tip of the tube. This is the cap, and this is a hooklike projection at the beginning of the second portion of the duodenum, a very queer-looking deformity. Then we looked back over our films and found some gas shadows above their usual position, high up in the region of the liver, rather linear-looking shadows.

DR. WELCH: Was gas in the colon prominent in the early examinations?

DR. HAMPTON: No; in the beginning we saw very little gas in the colon, and it was only some time later that we found it. She had a period of improvement, and at that time the gas passed into the colon.

DR. WELCH: Dr. Hampton has been extremely helpful, for a change, I should say. The failure of the Miller-Abbott tube to pass the pylorus usually does not mean anything at all. It may fail when the patient is perfectly normal. We have had several cases in which it refused to pass owing to an inflammatory lesion in the pylorus or just beyond it in the region of the duodenum, ascending colon or gall bladder. With the x-ray findings that Dr. Hampton has pointed out, one must, of course, pay a good deal of attention to the possibility that there was an inflammatory lesion just beyond the pylorus.

Obviously the patient was not improving, and for relief of obstruction it was consequently necessary to do an exploratory laparotomy. I wonder what the surgeon's preoperative diagnosis was. I should imagine that he probably considered adhesions as the probable source of the difficulty, because of the previous abdominal operation. The extreme completeness of the operative note is quite remarkable in view of the fact that the patient must have had dilated loops of small bowel making the exploration difficult. “Uniformly dilated small bowel could be observed down to the region of the ileocecal valve, and no areas of collapsed bowel were found.” That is *prima facie* evidence that the obstruction was lower than that. One would imagine that the “inflammatory process” was the same thing that Dr. Hampton pointed out in relation to the second portion of the duodenum. “There were no areas of fat necrosis, and although there was some scarring of the undersurface of the liver and around the duodenal cap, no mass could be outlined in the gall bladder or head of the pancreas.” In other words the operative findings in that site were not so remarkable as the x-ray findings.

This operative note makes the record more or less like an Agatha Christie story. Every organ

was explored and found to be normal, and yet we know one was not normal. In the first place, I think we might as well rule out unusual causes of ileus, such as metastatic carcinoma of the breast involving the spinal cord and producing a paralytic ileus. The story is not suggestive of that. Some renal lesions would produce paralytic ileus, but again that is unlikely, because this is a story of dynamic rather than paralytic ileus. We are therefore left with some lesion that must be intrinsic in the bowel itself, or pressing from the outside in such a fashion as to occlude it.

Our next problem is to localize the obstruction in the large bowel or small bowel. Obviously the operator believed he was dealing with a lesion in the splenic flexure, although it was impossible to feel it, a likely supposition because it is almost impossible to feel carcinoma obstructing the splenic flexure. There are a few features against large-bowel obstruction, however. In the first place, the pain was in the epigastrium when it began. It was followed immediately by vomiting, and the vomiting persisted for a period of six days. That is a very unusual story for acute large-bowel obstruction, in which vomiting may initially occur, but then is absent for a period of days. Finally the small bowel became loaded with fecal matter, and fecal vomiting finally occurred. In other words, from the story the obstruction was high in the small bowel. The guaiac negative stools are also of interest, and the x-ray picture shows absence of gas in the colon in the early stages of the disease, when the patient obviously had obstruction of the small bowel. In favor of large-bowel obstruction is the fact that the cecum and transverse colon were dilated, as well as the splenic flexure. That brings up the problem, then, of what it would be possible to overlook in the abdomen, so far as the intestinal tract is concerned, at the time of operation. Assuming the patient had a large bowel lesion, what would be overlooked? Most likely a carcinoma of the splenic flexure, possibly volvulus, especially of the cecum. That is ruled out, since the cecum was bound down by adhesions. Furthermore, volvulus of the sigmoid is ruled out by the fact that there was no distention of the descending colon. In other words, the only thing that could be overlooked in the large bowel, I believe, is carcinoma of the splenic flexure.

Could anything be overlooked in the small bowel? The operative note says the small bowel was observed down to the region of the ileocecal valve, and no areas of collapsed bowel were found. This does not exclude obstruction of the small bowel. I think probably all of us have seen, for

example, distention of the rectum beyond the obstructing lesion, and occasionally we have observed the same thing in the small bowel following inflammatory adhesions. There is distention not only proximal but distal to the point of obstruction after the disease has gone on for a certain length of time. I am inclined to believe that is so in this case, and I am also led to think that the small bowel was not observed inch by inch from the ileocecal valve to the ligament of Treitz. It seems to me that is the likeliest site for some thing to be overlooked.

What lesions in the small bowel could be overlooked? The patient obviously had no strangulating obstruction with volvulus and no intussusception, because she had no free fluid in the abdomen. Could there be some internal hernia that was not observed? That is entirely possible. Could she have had a tumor of the small bowel that was not observed, probably one of the benign type, such as carcinoid? Again, that is a possibility. Could she have had a foreign body obstructing the small bowel? If there were a foreign body, the commonest would be a gallstone. Dr. Hampton has kindly pointed out a lesion involving the biliary tree. The gas in the liver is very suggestive of a fistula between some part of the biliary tree and the duodenum, the prerequisite for a gallstone ileus. There are a number of features here that would go with the diagnosis of gallstone obstruction, such as the long story, the yellow skin, and the fact that there was definite obstruction of the small bowel; I shall therefore make that my diagnosis. The diagnosis is intestinal obstruction; this was probably due to a gallstone, and my second bet, which I believe is less likely, is a carcinoma of the splenic flexure.

CLINICAL DIAGNOSIS

Intestinal obstruction

DR. WELCH'S DIAGNOSIS

Intestinal obstruction, due to gallstone, or to carcinoma of the splenic flexure.

ANATOMICAL DIAGNOSIS

Intestinal obstruction, due to gallstone.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: To leave room for discussion, we had to stop this case at the point of the exploratory operation. As soon as the patient had convalesced sufficiently and the obstructive symptoms had disappeared, further investigation was done, which Dr. Hampton will show.

DR. HAMPTON: We subsequently outlined the

biliary tree with barium, but I thought that would make it too easy. I held out on you a little. The barium entered the common duct and gall bladder. We made the diagnosis, as Dr. Welch has, of perforation of the gall bladder into the duodenum, and gallstone ileus. The surgeon went in to remove the stone but could not find it. He did examine the small bowel thoroughly, even though the patient was an enormously fat person. Then he thought it must be in the colon at the splenic flexure, because that is where the obstruction was at the time of operation. We demonstrated a non-opaque stone by barium enema in the sigmoid after the operation.

DR. MALLORY: The day after the last x-ray plates were taken, the surgeon performed the final operation—a digital removal of the stone, which had finally reached the rectum.

DR. WELCH: What was the size of the stone?

DR. MALLORY: About 4 by 2.5 cm.—a very large one. It might easily have been permanently

stuck at the ileocecal valve. These patients with gallstone ileus, of course, invariably have a fistulous connection between the gall bladder and the duodenum. The stones are too large to pass through the cystic duct, and it is only by the formation of adhesions between the gall bladder and the duodenum, and perforation between the two viscera, that the stones make their way into the small bowel.

DR. HENRY H. FAXON: Is there anything in the history to suggest that the stone had been passed down?

DR. MALLORY: They did not get it very clearly. Certainly the initial part of the story is typical of small-bowel obstruction, and I do not believe that they were able to make a definite transition to large-bowel disease from the symptoms.

DR. HAMPTON: The surgeon did say the patient was getting better, but with a positive diagnosis of gallstone ileus he thought it advisable to attempt removal of the stone.

NATIONAL DEFENSE WEEK

For the past nineteen years, the period from Lincoln's Birthday to Washington's Birthday has been set aside as "National Defense Week." This period has been devoted to acquainting the public with the state and needs of our national defense, and was initiated, sponsored and carried on under the auspices of the Reserve Officers Association of the United States.

Largely owing to the activities of this organization, the public and Congress have been made aware of the need for an adequate Officers Reserve Corps and have been persuaded to appropriate funds for the training of this corps. Funds for this activity, as for all defense activities, were made available in a niggardly fashion until 1936,

when a somewhat more generous policy made it possible to initiate large-scale army maneuvers.

Throughout its history, this association has had an almost unique record of working wholeheartedly and unselfishly for national defense, with particular stress, of course, on the civilian components of the United States Army. In the development of the Officers Reserve Corps, the medical profession has taken a part of which we should all be proud. The first reserve officers in our army were a small band, numbering less than 300, organized in 1916 as the Medical Reserve Corps. This was the parent of the Officers Reserve Corps, which now has more than 100,000 officers of all arms and services on its rolls, including 15,000 medical officers.

In the activity of the association, doctors everywhere have given generously of their time and, indeed, have in many ways been the backbone of the entire movement. They have made possible the physical examination and immunization of officers throughout the last twenty years. They have spent time in the study of medical tactics—an activity that concerns approximately half the medical officers of any armed force. In Metropolitan Boston, as in other cities, a large medical chapter of the association has provided a nucleus for activities and training of the Medical Department, and two doctors have been presidents of the Massachusetts department of the association.

By July 1, it is expected that our expanded army will have about 9000 medical officers serving for "a year's training." Of these, about two thirds will come from the ranks of the Officers Reserve Corps and will be, for the most part, men who have qualified for their positions by activities outside their professional duties. It seems desirable, at this time, to call attention to the devoted work of those men who are sacrificing a year of their time to occupy important tactical and administrative positions in the Medical Department of our expanded army, so that adequate training may be provided for the younger medical officers and for the selectees assigned to the Medical Department as enlisted personnel. The sacrifice for those who have attained field-officer rank in the

Officers Reserve Corps is even greater, and they have already proved their value in the national-defense program by their current activities. It is to be hoped that their successors, who are now getting their first taste of army training, will grow to appreciate the public service that this group has rendered and is rendering, and will carry on so that the Medical Department will be properly manned not only professionally but in regard to the administrative and tactical framework that is necessary for bringing medical service to the sick and wounded.

WAR MEDICINE

THE appearance in late January of the first issue of a bimonthly publication, *War Medicine*, represents a response on the part of the Division of Medical Sciences of the National Research Council and of the trustees of the American Medical Association to a demand for information concerning the medical problems brought about by the present emergency.

During the spring of 1940, at the instigation of the Surgeons General of the United States Army and Navy, the Division of Medical Sciences of the National Research Council created a number of committees, composed of outstanding physicians, to advise in regard to what should be adopted as routine procedures in particular branches of medicine. As pointed out in an article in the current issue of *War Medicine*, there are, at the moment, six committees, covering medicine, surgery, aviation medicine, transfusions, chemotherapeutic and other agents, and neuropsychiatry, with subcommittees for the more detailed specialties of medical practice and research, especially as they relate to the broader aspects of military medicine.

A seventh committee, the Committee on Information, was created for the purpose of making available to the governmental services in particular and to the medical profession in general the recommendations of the advisory committees and pertinent information gleaned from all sources. In addition to various monographs, manuals and bulletins, this committee suggested the publication of a periodical devoted wholly to medical prepared-

ness and war medicine, an undertaking to which the trustees of the American Medical Association generously agreed. *War Medicine* is the result, with the members of the Committee on Information constituting the editorial board.

Since many of the medical problems of preparedness and war have little to do with those of civilian practice, this journal should prove to be of great value to all physicians who have or may become responsible for the medical care of members of the services and of industrial workers and their families—and this is likely to include every physician in the United States.

OBITUARY

FRED ELLSWORTH CLOW

1881–1941

The practice of medicine, thank God, can produce strong men: men able to spread the gospel of truth and integrity over the four corners of the land. Fred Ellsworth Clow was one of these.

He graduated from the Harvard Medical School in 1904, a New Englander all the way back to the beginning and proud of it. He saw things straight and never compromised with his conscience.

He served as intern at the Elliott Hospital in Manchester and then returned to Wolfeboro, where he belonged. There is a Clow Hill at East Wolfeboro, and an old homestead, going back, I believe, to that Clow who left Wolfeboro in 1775 to go to the War.

Fred Clow became a tower of medical strength in his part of New Hampshire. He did everything that could be expected of an intelligent, energetic, vitally alive doctor. He had a large practice. On the day of his funeral, flags all over the town were at half mast, and the schools and stores and offices of the village were closed. No one in the town could go about his ordinary business at such a time.

Fred Clow had a hand in almost everything in the way of progress that was going on in his community. He had been secretary-treasurer of the New Hampshire Board of Registration in Medicine. He took an active interest in the affairs of the New Hampshire Medical Society, serving as speaker of the House of Delegates and on a variety of committees. He was health officer in Wolfeboro, and at one time, president of the Carroll County Medical Society. He was a deacon of the First Congregational Church and had served as presi-

dent of the Wolfeboro Rotary Club. Of all his accomplishments he was proudest of having built up the Huggins Hospital into a model community hospital, perfectly equipped and effectively run.

He believed in keeping up with the times. He regularly attended the meetings of the American Medical Association and the American College of Physicians, and he went abroad a couple of times to see what was going on in the medical world of Europe. Hence he had a wide medical friendship.

He had an incisive way of speaking, with a shrewd ability to separate what was false from what was true; and an insight into human nature so that he could ferret out dishonesty and chicanery. He was an admirer of Abraham Lincoln and a keen student of his writings. Perhaps he acquired some of Lincoln's characteristics by being so familiar with them.

Fred Clow died when he was only fifty-nine years old. But in a sense he is not dead, for his influence will be felt in New England medicine for many years to come.

R. F.

MEDICAL EPONYM

VON GRAEFÉ'S SIGN

This was described by Albrecht v. Graefe (1828-1870) at a meeting of the Berlin Medical Society on March 9, 1864, and was reported in the *Deutsche Klinik* (16:158, 1864), under the title "Ueber Basedow'sche Krankheit [Concerning Basedow's Disease]." A portion of the translation follows:

When we cause the healthy person to look up and down, the upper eyelid moves correspondingly. In those suffering with Basedow's disease, this motion is almost completely abolished or reduced to a minimum: that is, when the cornea is turned downward, the upper eyelid does not follow. This is not a direct result of the exophthalmos, because in the presence of tumors of the orbit or other causes of protrusion, the symptom is frequently absent, although in very marked degrees the motions of the lid are naturally interfered with. On the other hand, it is present in the mildest degree of exophthalmos in Basedow's disease. . . . It is apparently to be regarded as a peculiar disturbance of the innervation of the muscles of the eyelid.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

RESOLUTION ON THE DEATH OF DR. EDWARD MELLUS

The medical profession, as well as the entire citizenry of Newton, has suffered a severe loss in

the sudden passing of Dr. Edward Mellus on December 7, 1940.

Dr. Mellus was born in Zumbrota, Minnesota, sixty-eight years ago, and when a boy lived in Newton for two years attending the Newton High School with the Class of 1890. He attended the fiftieth reunion of that class two days before his death. He graduated from Worcester High School in 1891, Harvard College in 1895 and Harvard Medical School in 1898. He enlisted at once in the Medical Corps of the United States Army and served in Cuba during the Spanish-American War.

On his return to Massachusetts he became resident physician at several state hospitals for the insane, including Mattapan, Foxboro and Worcester. He next assumed the management of the Paine Sanitarium at West Newton, and later moved this institution for nervous and mental cases to the Hopewell estate on Waverley Avenue. He retired from active practice in 1929, but still was often called for consultation for mental and nervous conditions. He was the consulting psychiatrist for the Newton Hospital from 1929 until his death.

His activities were not limited to professional interests. He served as a member of the Newton Planning Board and of the Newton Board of Health. He was a 32nd degree Mason, a Shriner and member of the Rotary Club of Newton, of the Hunnewell Club, of the Newton Medical Club, of which he was a past president, of the Massachusetts Medical Society and of the New England Society of Psychiatry.

He was richly endowed by nature, education and experience and contributed generously to every organization to which he belonged. He will long be remembered as a genial companion, possessing rare wit and ready repartee, which enlivened any assembly at which he was present. But the greatest contribution was his effort to improve the diagnosis, care and possible relief of that large and much misunderstood group who suffer from mental deficiencies and diseases. His kindly manner and gentle technic, sustained by a wealth of scientific knowledge and genuine sympathy for the afflicted, endeared him to his professional associates, the public and, most of all, to that special group who consulted him for advice and assistance.

RAYMOND S. TITUS, M.D., *Secretary*
330 Dartmouth Street
Boston

FORCEPS DELIVERY IN A PATIENT WITH MITRAL STENOSIS

Mrs. B. P., a twenty-seven-year-old primipara, was first seen on December 29, 1939, when she was approximately eight weeks pregnant.

The family history was noncontributory. The patient had had rheumatic fever at the age of twelve and had also had the usual childhood diseases. The tonsils had been removed. Catamenia began at fourteen, were regular with a twenty-eight-day cycle and lasted seven days without pain. The last regular period began on November 4, making the expected date of confinement, August 11, 1940.

Physical examination at the time of her first visit showed a well-developed and well-nourished woman. The weight was 124 pounds. The heart showed definite evidence of disease. The lungs were clear and resonant; there were no rales. The blood pressure was 160 systolic, 60 diastolic. Vaginal examination showed that the fundus was anterior and that the patient was probably pregnant. Because of the definite cardiac abnormality the possible seriousness of the situation was discussed with the patient and a consultation with a cardiologist was advised and accepted.

The consultant's note read as follows: "The patient has a moderately enlarged heart, a systolic murmur, and a late crescendo mitral diastolic murmur. The blood pressure is 160 systolic, 40 to 10 diastolic. She has, then, mitral stenosis, with aortic regurgitation. The electrocardiogram is not informative." The consultant considered it not unreasonable for the patient to continue pregnancy, since she had had no history of decompensation. He advised her to observe the usual restrictions of a cardiac patient and to be followed closely throughout pregnancy.

The patient was seen by the obstetrician and the cardiologist frequently during her pregnancy, which progressed normally. The total weight gain was 17 pounds. There were no cardiac symptoms except that during a cold she developed a good deal of discomfort over the precordium, an elevation of the pulse and a cough.

On July 31, 1940, following an office visit, the patient had a slight bloody discharge and was sent into the hospital. The next morning the

membranes ruptured spontaneously, and good labor began about noon. She was given 1/6 gr. morphine and 1/200 gr. scopolamine. At 1:30 p.m., the cervix was extremely soft, flat and dilated sufficiently to admit three fingers. The progress of labor was not rapid, and she was delivered shortly after 4:00 p.m. by simple forceps under nitrous oxide, oxygen and ether anesthesia of a living male child weighing 8 pounds, 1 ounce. The convalescence was uneventful.

The patient was seen in the office on September 25. The condition of the heart was as before; there was no evidence of increased damage.

Comment. This case of heart disease was recognized by the obstetrician and immediately referred to a cardiologist. The patient was advised to take much more rest than the ordinary patient from the very beginning of her pregnancy, and at times she was in bed the better part of two or three days every week. At no time was there any evidence of decompensation.

Induction of labor was entertained when the patient was approximately thirty-eight weeks pregnant. Spontaneous labor, however, began the next day, and although the labor was not so short as had been anticipated, the heart withstood the strain, and there were no cardiac complications. The patient was given morphine, scopolamine and nitrous oxide, oxygen and ether anesthesia, but no other medication.

The present opinion that labor in cardiac patients rarely induces decompensation was borne out in this case. Had the head not been in the pelvis or had labor started with an unobliterated cervix, cesarean section would have been considered. When the head is well engaged and the cervix is obliterated and propitious before labor starts, vaginal delivery is now generally considered the more conservative procedure.

MEDICAL POSTGRADUATE EXTENSION COURSES

The following sessions, given by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, have been arranged for the week beginning February 23:

MIDDLESEX EAST

Tuesday, February 25, at 4:15 p.m., at the Melrose Hospital, Melrose. Head Colds and Complications. Instructor: Charles T. Porter. Walter H. Flanders, *Chairman*.

MIDDLESEX SOUTH

Tuesday, February 25, at 4:00 p.m., at the Cambridge Hospital, Mt. Auburn Street, Cambridge. Recent Advances in Medical Therapeutics. Instructor: G. Philip Grabfield. Dudley Merrill, *Chairman*.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

NORFOLK

Thursday, February 27, at 8 30 p.m., at the Norwood Hospital, Norwood Pediatric Case Discussions Instructor Louis K. Diamond Hugo B. C. Riemer, *Chairman*

NORFOLK SOUTH

Monday, February 24, at 8 30 p.m., at the Quincy City Hospital, Quincy Diagnosis, Treatment and Prognosis of Central Nervous System Syphilis Instructor Francis M. Thurmon David L. Belding, *Chairman*

SUFFOLK

Thursday, February 27 at 4 30 p.m., in John Ware Hall, Boston Medical Library Obstetric Complications with Case Histories and Clinical Problems Instructor Judson A. Smith Reginald Fitz, *Chairman*

NEW HAMPSHIRE MEDICAL SOCIETY

DEATHS

CLOW—FRED E. CLOW, M.D., died suddenly Saturday January 4, at his home in Wolfeboro, in his sixtieth year. He was born in East Wolfeboro, the only son of Stephen W. and Carrie (Canney) Clow. He graduated from Brewster Academy in 1900 and received his degree from Harvard Medical School in 1904. Through his vision, foresight and energy, the Huggins Hospital was established in 1907, and it was largely through his effort that the present modern hospital was erected in 1925.

Dr. Clow was secretary treasurer of the New Hampshire Board of Registration in Medicine, trustee of Brewster Academy, fellow of the American College of Physicians and member of the American Medical Association, the New Hampshire Medical Society and the Carroll County Medical Society.

Survivors are four children: Mrs. W. J. Paul Dye, of Wolfeboro; Mrs. Joseph Culick, of Exeter; and Stephen E. Clow and Dr. John H. Clow, of Rochester.

HUBBARD—OSMON H. HUBBARD, M.D., of Keene, aged seventy-eight, died suddenly at his home on January 5. He was born in Sullivan, July 23, 1862, a son of Mr. and Mrs. George C. Hubbard. He graduated from McGill University Faculty of Medicine in 1888, and had practiced in Fitzwilliam, Walpole and Needham, Massachusetts, and in Gilsum and Keene, New Hampshire. Dr. Hubbard had specialized in diseases of the nose, throat and ears for many years and had given up this more active work to become pathologist at the Elliot Community Hospital about a year ago. He was a fellow of the New Hampshire Medical Society and of the American Medical Association.

Dr. Hubbard is survived by one brother, Charles L. Hubbard of Jamaica Plain, Massachusetts.

MacKENZIE—NICHOLAS Y. B. MacKENZIE, M.D., of Andover, died November 27, 1940. He was in his sixty-sixth year.

Born in Ellsworth, Maine, Dr. MacKenzie received his degree from Dartmouth Medical School in 1901. He interned in New York and Boston hospitals and settled in Andover in 1917, after having practiced in Salisbury and Gilmanton.

His widow and six children survive him.

MISCELLANY

PHYSICIANS GROUP OVER THE TOP

The Physicians Group more than contributed its quota in the recent drive of the Greater Boston Community Fund. With the total set at \$20,500, approximately seven hundred physicians contributed \$20,795, or 101.4 per cent of the quota.

JOHN PHILLIPS MEMORIAL AWARD

On the recommendation of the Committee on Fellowships and Awards the Board of Regents of the American College of Physicians, by unanimous resolution, has voted that the John Phillips Memorial Medal for 1941 be awarded to Dr. William C. Stride, associate professor of research medicine, University of Pennsylvania, for his significant contributions to the knowledge of anemia, cyanosis and the physical chemistry of hemoglobin and more especially for his recent studies on the subject of fat metabolism in diabetes mellitus.

This award was established on October 27, 1929, to be given periodically for some outstanding piece of work in internal medicine. Internal medicine is interpreted to include not only clinical science, but all subjects that have a direct bearing on the advance of clinical science. The work must be done in whole or in part in the United States or in Canada.

Nominations for the award are made to the Committee on Fellowships and Awards of the American College of Physicians. The recipient must file a written account of his work, and must present his results as a paper before the annual session, at which time the award of a bronze medal is made by the president.

AID FOR PHYSICIANS' CHILDREN IN ENGLAND

The Physicians' Wives League of Greater New York, 75 East 86th Street, has raised among its members \$150 which has been contributed through the Save the Children Federation to assist five physicians' children among the child victims of the war in Great Britain. This donation is a part of the money transmitted to England in the federation's nation-wide endeavor to provide American godparents for British and other children now being cared for in England at the rate of \$2.50 per month for each child. Nearly 6000 children who have been bombed from their own homes or who have otherwise suffered in the war now have this American godparent assistance.

Many physicians, surgeons, nurses and others connected with the profession are among the godparents, who represent every state in the Union. The federation's headquarters are in the Metropolitan Tower, 1 Madison Avenue, New York City.

CORRESPONDENCE

GONOCOCCUS COMPLEMENT FIXATION TESTS

To the Editor: At its meeting on January 21, the Public Health Council voted that in view of the rapidly increasing burden of work at the Wassermann Laboratory and the questionable value of the gonococcus complement fixation test the routine performance of these tests should be discontinued. In order to give physicians due notice of this action it is planned to continue the routine performance of these tests on request through the month of Feb-

ruary. Beginning March 1, however, these tests will no longer be performed.

PAUL J. JAKMAUH, M.D.,
Commissioner of Public Health.

State House,
Boston.

REQUEST FOR INFORMATION IN REGARD TO THE NUMBER OF DIABETIC CHILDREN IN MASSACHUSETTS

To the Editor: There are many diabetic children under the age of fifteen years in Massachusetts, but how many no one knows. The number is increasing, because formerly they lived only one or two years but now they enter manhood and womanhood.

If we knew how many of these children there were in the State we should all be in a better position to advise as to their future.

I should consider it a great favor if any of your readers would notify me if they now know or have under their care any diabetic children under the age of fifteen. To save duplication I should appreciate the following data:

1. Name or initials of the child
2. Residence (city or town)
3. Sex
4. Race or nationality
5. Year of birth (age)
6. Year of onset of diabetes (duration)

Signed (physician or hospital)
Address

On receipt of a postal card I shall gladly send cards made out as above to any physician or hospital, but the number of children in the State is so small that I hesitate to send out letters like this with envelopes for reply to each of the 7839 physicians in Massachusetts.

ELLIOTT P. JOSLIN, M.D.

81 Bay State Road,
Boston.

REPORT OF MEETING

HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on November 26, 1940, with Dr. Elliott C. Cutler presiding.

The first case, presented by the Surgical Service, was that of a young man with a history compatible with that of peptic ulcer, who entered with signs and symptoms of diffuse peritonitis. Roentgenograms demonstrated air under both diaphragms, and an operation was performed. At that time a perforation of a Peyer's patch, secondary to typhoidal infection, was found. The abdomen was closed without drainage, and the patient was put on Ochsner's regimen, with Wangenstein drainage, 100 per cent oxygen, Fowler's position, and morphine at regular intervals. The serum protein never fell below 5.9 gm. per 100 cc. The patient was given several blood transfusions and made a satisfactory recovery.

The second case, presented by the Medical Service, was that of a thirty-three-year-old woman who had drunk moderate amounts of alcohol for fifteen years and extremely large amounts for the previous five or six years. She had eaten very little food for a few months, and had noticed nausea and vomiting for the last five days. There had been increasing constipation for six months, with an increase in girth for one month and obstipation for seven days. She had recently been disorientated and noisy at

night. Physical examination revealed puffy cheeks, with telangiectases. The patient was disorientated, with visual hallucinations and confabulation. The scleras were jaundiced, horizontal eye movements were poor, the tongue was smooth and red, and there were pulmonary emphysema, doughy edema and an enlarged abdomen. The temperature was 101°F., the pulse 140, and the respirations 20. The icteric index was 15, the venous pressure 130 mm. of water, the circulation time 14 seconds, the red-cell count 3,500,000 with a hemoglobin of 85 per cent, and the white-cell count 17,000. The urine had a slight trace of albumin, the white blood cells in the sediment increasing from 5 to 50 per high-power field after admission. The blood urea nitrogen, originally 74 mg. per 100 cc., rose to 91 mg. Further examination of the abdomen revealed distended loops of bowel, normal peristalsis, and tenderness in the right upper quadrant, with no liver dullness. There were hypesthesias of the lower arms and legs, a loss of fine movements, sluggish tendon reflexes and tender calf muscles. The course under intensive vitamin therapy was one of clinical improvement, although there were still some hallucinations. Dr. Elliott C. Cutler suggested that the gas in the bowel might be on a neurologic basis and that novocain injection of the spinal cord should probably have been tried. Dr. John Romano stated that the patient had a definite Korsakoff syndrome, with a question of Wernicke's syndrome. Dr. Soma Weiss remarked that abdominal distention from acute or chronic alcoholism is not uncommon and may possibly be of neurologic origin. On the other hand, alcoholic patients may rupture an ulcer or appendix during a spree, presenting themselves later with distention and no spasm.

Dr. Jacob Fine, of the Beth Israel Hospital, addressed the society on "Clinical and Experimental Studies in Intestinal Obstruction." He pointed out that to simplify the study of intestinal obstruction it is best to omit a consideration of its complications, that is, strangulation and peritonitis. These are of clinical importance, but serve only to confuse an understanding of the basic processes involved. Most of the experimental work on the etiology of intestinal obstruction centers around a search for a circulating toxin, or an effort to explain all the phenomena involved by water and electrolyte imbalance. The evidence for a toxin remains unconvincing, and clinical experience has demonstrated the inadequacy of therapy for chloride, water and sodium imbalance. Uncomplicated high intestinal obstruction is consistent with life until death from starvation ensues, so long as water and electrolytes are adequately replaced. If the deficiency of these substances were the crucial factor in uncomplicated intestinal obstruction, it should be possible to maintain life in low obstruction of the small intestine for as long a time by similar therapy. Since this has not been possible, the assumption is that there is a basic difference between the two levels of obstruction. That difference consists in the ability of the bowel to decompress itself more effectively when the obstruction is high than when it is low, so that what seems of primary significance is the increase in intraintestinal pressure. The large literature on the effects of increased pressure is confusing because of conflicting results. Many of the conclusions drawn are not convincing for the reason that the pressures used were far in excess of those known to exist clinically in the intestine during obstruction. Another difficulty is the variety of technics utilized. Dr. Fine presented the following simple procedure, which has formed the basis of his studies: the small bowel or the stomach and small bowel of a cat, free of fluid and gas, is tied off at both ends, thus

preventing access to swallowed air or to fluid, except se- cretions, in other words the intestine is converted into an empty, closed loop

Such a loop remains substantially free of gas and fluid after one or more days. Examination of such loops shows some edema and engorgement at the cecum end. Other- wise the bowel is normal, and there is no peritonitis. If a similar loop, with the stomach excluded, is distended with nitrogen under slight positive pressure, the volume of gas injected remains about the same after twenty four hours, if the animal is caused to breathe pure oxygen continuously from the time of inflation of the loop, the volume of gas after twenty four hours averages 40 per cent of the original. The amount of fluid recovered from such loops, whether the animals breathe air or oxygen, is negligible. If the pressure in an empty collapsed loop is gradually raised for six hours by a constant stream of air or nitrogen and if the loop is allowed to decompress itself spontaneously, the pressure falls slightly or moderately and death results in an average of fourteen hours. The survival time is inversely proportional to the height of the final pressure. But if in a similar group of experi- ments the animal is given pure oxygen to breathe at the time when spontaneous decompression begins, the intra- intestinal pressure falls steadily toward zero, and the sur- vival time is very much prolonged. This effect of oxygen cannot be attributed to the general sustaining qualities of oxygen but, as a number of previous publications have shown, to the fact that breathing pure oxygen facilitates an increased rate of absorption of nitrogen. The differ- ence in the average amount of peritoneal and intraintes- tinal fluid between the animals breathing air and oxygen was 16 cc. so that the more rapid death of the air breathing animals cannot be explained on the basis of a greater fluid loss. In previous experiments in which a va- riety of foods were introduced into such loops, the time of survival was proportional not so much to the fluid loss or to the volume of gas as to the rapidity with which ten- sion developed. In general the shortest survival times were associated with the highest tensions. It is obvious that the kind and amount of food present in the intestine at the time obstruction begins, or swallowed during the course of the process, determine to a considerable extent the intraintestinal pressure and the progress of the dis- ease.

Death occurred in the experiments with empty loops distended with nitrogen in the absence of a significant loss of water and electrolytes, plasma or blood into the perito- neal cavity or bowel. The total fluid recovered in air breathing animals from the peritoneal cavity, bowel wall and bowel lumen averaged 37 cc., in the oxygen breathing animals 21 cc., and in control animals with undistended loops 11 cc. Such fluid losses cannot account for death even though they may be regarded as contributory.

In a search for other causes for the death produced by increased intraintestinal pressure, the problem was viewed in terms of the effects of distention, which is a necessary concomitant of increased pressure. The femoral venous pressure showed a marked rise in all experimental an- imals with distention. But no clear evidence of fluid loss into the lower extremities was demonstrable. A simulta- neous study of plasma volume changes, however, showed that plasma was being lost in substantial quantities. In dogs the loss reached as much as 55 per cent, which is sufficient to explain death. Occasionally such a loss was observed when only a few feet of small intestine were distended so that the factor of distention of the perito- neal cavity seems to have been excluded. Plasma loss in peritoneal distention was occasionally observed, but the

loss was usually not sustained. Furthermore, distention of the colon in dogs, which produces a marked distention of the peritoneal cavity, was not accompanied by plasma loss. The plasma loss in obstruction of the small intestine was therefore considered specific for that part. Indeed, at least so far as local plasma loss is concerned, clinical ob- servation shows that an excess of peritoneal fluid is not a prominent factor in obstruction of the colon, but is not in frequently seen in advanced small bowel obstruction.

It therefore appears that although part of the plasma is lost in the gastrointestinal tract and peritoneal cavity, the amount recoverable from these areas is only a fraction of the total amount lost, which, in animals at least, is exten- sive enough to explain death.

That plasma loss is a direct effect of distention was shown in the recovery of plasma volume following the institution of decompression. Plasma replacement in a group of dogs definitely prolonged their lives for a period comparable to that of undistended dogs otherwise treated in the same fashion. Replacement of lost plasma by intra- venous saline did not prolong life. Some of the results detailed above, especially the loss of plasma during ob- struction with distention and return of lost plasma on re- lief of the distention, have been confirmed in patients.

Acute plasma loss is common to many rapidly fatal con- ditions but it cannot be regarded as a nonspecific terminal event in intestinal obstruction, because the loss of plasma in such cases is large and significant from the very onset of the distention. The analogy between intestinal obstruc- tion and traumatic shock recalls various efforts to explain shock on a neurogenic basis. The evidence for the protec- tive effect of denervation of distended loops was not con- firmed in the experiments in which the denervation con- sisted of removal of the celiac ganglion and division of both vagus nerves.

SPECIAL NOTICE

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE ON STATE AND NATIONAL LEGISLATION

The following bills are scheduled for hearings the week of February 24

February 25

S 485 (Public Health) Petition of Robert T. Monroe proposing legislation relative to admission to licensed practice of medicine. This bill makes requirements for registration in medicine the same as the National Board of Medical Examiners. *Favored*

H 1564 (Public Health) Same as S 485

S 560 (Public Health) Petition of Bertram A. Har- ris and others for legislation relative to the qualifications of applicants for registration as qualified physicians and examinations thereof. This bill annuls the power of the Approving Authority. *Opposed*

H 114 (Public Health) Bill (accompanying H 113, recommendations of the Board of Registration in Medi- cine) relative to providing for the annual registration of physicians and the biennial publication of the list of physicians duly registered—the perennial annual registration bill. *Opposed*

H 115 (Public Health) Bill (accompanying H 113, recommendations of the Board of Registration in Medi- cine) relative to the recording of the certificate of regis- tration of a qualified physician by the town clerk. This bill only adds a new penalty to existing laws. *Opposed*

H 116 (Public Health) Bill (accompanying H 113,

recommendations of the Board of Registration in Medicine) relative to establishing a special commission to investigate and study the advisability and practicability of requiring special qualifications of all physicians who engage in the practice of surgery. This should be handled by the Massachusetts Medical Society; it is a matter of education rather than one of legislation. *Opposed.*

H. 272 (Public Health). Petition of Harold W. Sullivan that there be appropriated from the treasury of the Commonwealth the sum of twenty-five thousand dollars to provide for an investigation by the Board of Registration in Medicine relative to the practice of medicine. Under the present law the Board has adequate power to investigate, and funds should be obtained in the usual way. *Opposed.*

H. 611 (Public Health). Petition of James A. Vahey for legislation relative to the qualifications for applicants for registration as qualified physicians. This bill postpones the effective date of the Approving Authority from 1941 to 1945. *Opposed.*

H. 1229 (Public Health). Petition of Domenic Staziani for legislation to protect persons needing medical care and relative to the registration of students of medicine. *Opposed* (as drawn).

February 26

S. 502 (State Administration). Petition of Joseph C. Basso for legislation to provide for the regulation of the practice of osteopathy and for the establishment of a state board of osteopathic examination and registration. *Opposed.*

February 27

H. 609 (Public Health). Petition of Annie D. Brown for legislation to provide further for regulating the practice of physicians and surgeons. A perennial impracticable bill. *Opposed.*

H. 610 (Public Health). Petition of Annie D. Brown for amendment of the law regulating the practice of physicians and surgeons in certain cases. A perennial impracticable bill. *Opposed.*

H. 1838 (Public Health). Petition of J. Arthur Moriarty and others for legislation to provide for nonprofit medical-service plans. The White Cross bill. *No action.*

NOTICES

BOSTON GASTROENTEROLOGICAL SOCIETY

There will be a meeting of the Boston Gastroenterological Society in the amphitheater of the Beth Israel Hospital on Wednesday, February 26, at 12 noon. An x-ray conference on gastrointestinal diseases by Dr. Samuel A. Robins and his associates will take place.

GREATER BOSTON MEDICAL SOCIETY

The next meeting of the Greater Boston Medical Society will take place on Tuesday, March 4, in the auditorium of the Beth Israel Hospital at 8:15 p.m.

PROGRAM

Factors that May Induce Cardiac Infarction. Dr. Ernst P. Boas, assistant professor of medicine, Columbia University College of Physicians and Surgeons. Discussion will follow by Drs. Herman L. Blumgart, Samuel A. Levine and Samuel H. Proger.

BOSTON MEDICAL HISTORY CLUB

The next meeting of the Boston Medical History Club will take place on Monday, February 24, at the Boston Medical Library, 8 Fenway, Boston, at 8:15 p.m. Dr. Alan R. Moritz will speak on "Peaks in the History of Legal Medicine."

All interested persons are cordially invited to attend.

JEWISH MEMORIAL HOSPITAL

There will be a staff meeting of the Jewish Memorial Hospital in the hospital auditorium, 45 Townsend Street, Roxbury, on Thursday, February 27, at 8:30 p.m.

PROGRAM

Some Important Errors in the Diagnosis of Heart Disease. Dr. Samuel A. Levine.

Collation.

The medical profession is invited to attend.

JOHN T. BOTTOMLEY SOCIETY

The regular monthly meeting of the John T. Bottomley Society will be held in the Out-Patient Building of the Carney Hospital on Tuesday, March 4, at 11:30 a.m. Dr. Herbert Finn will speak on "Some Recent Advances in Surgery."

Physicians and students are cordially invited to attend

TUFTS COLLEGE MEDICAL SCHOOL ALUMNI ASSOCIATION

The forty-seventh anniversary of the Tufts College Medical School Alumni Association will be celebrated at its annual dinner on Wednesday, March 26, at 7 p.m., at the Hotel Somerset, Boston.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS, UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Salem	March 3	Harold C. Bean
Haverhill	March 5	William T. Green
Lowell	March 7	Albert H. Brewster
Gardner	March 11	Mark H. Rogers
Brockton	March 13	George W. Van Gorder
Pittsfield	March 17	Frank A. Slowick
Northampton	March 19	Garry deN. Hough, Jr.
Worcester	March 21	John W. O'Meara
Fall River	March 24	Eugene A. McCarthy
Hyannis	March 25	Paul L. Norton

NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting of the New England Roentgen Ray Society will be held in John Ware Hall, Boston Medical Library, on Friday, February 28, at 8:30 p.m.

PROGRAM

Spinal-Canal Block as Demonstrated by Air Myelography. Dr. Wendell C. Hall.
Heavy-Metal Lines in Epiphyseal Ends of Growing Bones. Dr. Ralph T. Ogden.
Osteitis Tuberculosis Multiplex Cystica. Dr. Max Kliman.
Roentgen Diagnosis in Neurocutaneous Syndromes. Dr. Gilbert W. Heublein.
Atypical Bone Tumors. Dr. Douglas J. Roberts.

NEW ENGLAND OTO-LARYNGOLOGICAL SOCIETY

The regular spring meeting of the New England Oto-Laryngological Society will be held on Wednesday, March 19, at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, at 4 p.m. The evening program will be devoted to a symposium on "The Management of Some of the Complications Arising from Acute and Chronic Otitis Media." Discussion will follow by Drs. Harold Tobey, Charles T. Porter, Maxwell Finland, Champ Lyons, W. Jason Mixter and Charles S. Kubik.

MASSACHUSETTS DEPARTMENT OF CIVIL SERVICE AND REGISTRATION

Medical Inspector of Schools and Working Children, Health Department, North Adams, \$1500 a Year

Director of State Civil Service, Ulysses J. Lupien, has recently announced that a competitive examination is to be held on April 5 in order to find eligibles for appointment to the position of medical inspector of schools and working children, Health Department, North Adams.

The entrance requirements are as follows: applicants must be registered physicians under the State Board of Registration in Medicine. The subjects and weights of the examination are as follows: training and experience, 2; practical questions, 3; total, 5. Applicants must obtain a grade of 70 per cent in each subject in order to become eligible. The last date for filing applications is Saturday, March 22, at 12 o'clock noon.

SIXTH ANNUAL POSTGRADUATE INSTITUTE OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY

The Sixth Annual Postgraduate Institute of the Philadelphia County Medical Society will take place from March 31 to April 4 at the Bellevue-Stratford Hotel, Philadelphia. "Symposiums on Modern Therapy" will be the title of the meeting. Further information may be obtained by writing to Postgraduate Institute, Philadelphia County Medical Society, 301 South Twenty-First Street, Philadelphia, Pennsylvania.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, FEBRUARY 23

SUNDAY, FEBRUARY 23

- 11 a.m. Fatigue and Health Dr. David B. Oll Free public lecture Harvard Medical School Building D
- 11 p.m. Your Nose and Your Throat What about them? Or Edmund J. Butler Cambridge Hospital Margaret Jewett Hall

MONDAY, FEBRUARY 24

- 12:15-1:15 p.m. Clinicopathological conference Peter Bent Brigham Hospital amphitheater
- *8:15 p.m. New England Heart Association Beth Israel Hospital
- *8:15 p.m. Peaks in the History of Legal Medicine Dr. Alan R. Moritz Boston Medical History Club Boston Medical Library 8 Fenway

TUESDAY, FEBRUARY 25

- *9-10 a.m. Ray demonstration Or Alice Ettinger Joseph H. Pratt Diagnostic Hospital
- 12:15-1:15 p.m. Clinicoradiological conference Peter Bent Brigham Hospital amphitheater

WEDNESDAY, FEBRUARY 26

- *9-10 a.m. Hospital case presentation Or S. J. Thannhauser Joseph H. Pratt Diagnostic Hospital
- *12 m. Clinicopathological conference Children's Hospital
- 12 m. Boston Gastroenterological Society Beth Israel Hospital
- *2-4 p.m. Hematuria and Dysuria Ors W. C. Quinby and F. A. Stead Peter Bent Brigham Hospital.

THURSDAY, FEBRUARY 27

- *8:30 a.m. Combined clinic of the medical, surgical, orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital, at the Peter Bent Brigham Hospital
- *9-10 a.m. Gastrointestinal clinic Or. K. S. Andrews Joseph H. Pratt Diagnostic Hospital
- 8:15 p.m. New England Section of the American Urological Association Harvard Club of Boston
- *8:30 p.m. Some Important Errors in the Diagnosis of Heart Disease Dr. Samuel A. Levine Jewish Memorial Hospital, 45 Townsend Street, Roxbury

FRIDAY, FEBRUARY 28

- *9-10 a.m. Amenorrhea and Abnormal Bleeding Dr. J. V. Meigs Joseph H. Pratt Diagnostic Hospital
- 8:15 p.m. Massachusetts Memorial Hospitals Evans Memorial Auditorium
- 8:30 p.m. New England Roentgen Ray Society Boston Medical Library, 8 Fenway

BOOK REVIEWS

Manual of Medical and Surgical Emergencies. Edited by J. C. Geiger, M.D. 8th, cloth, 199 pp. San Francisco: J. W. Stacey, Incorporated. \$2.50.

This work is a compilation of facts about medical and surgical emergencies in a single, handy volume. The

need for such a book is rather limited. It should be of most assistance to the beginner on an emergency service of any large city hospital, where quick decisions are so often necessary.

Simplified Diabetic Manual, with 163 International Recipes (American, Jewish, French, German, Italian, Armenian and so forth). By Abraham Rudy, M.D. Introduction by Frederick M. Allen, M.D. 8°, 216 pp., with tables, charts and illustrations. New York: M. Barrows and Company, Incorporated, 1940. \$2.00.

The new edition of this useful manual, formerly entitled *Practical Handbook for Diabetic Patients*, presents many diet forms adapted to the dietary customs of patients of many nationalities. The description of the use of protamine zinc insulin and crystalline insulin, together with a simple discussion of the vitamins, will aid the physician in securing the necessary co-operation of diabetic patients.

The Diagnosis and Treatment of Pulmonary Tuberculosis. By John B. Hawes, 2d., M.D.; and Moses J. Stone, M.D. Second edition. With a foreword by Richard C. Cabot, M.D. 8°, cloth, 260 pp., with 75 illustrations. Philadelphia: Lea and Febiger, 1940. \$2.75.

Following the death of the senior author, this book now appears in a second edition, revised by Dr. Stone. It is still a "brief and concise textbook," as the first edition was intended to be, and will serve very well as a practical guide for the medical student and the practitioner. Changes in this edition include new chapters on allergy and immunity and on mental aspects of the disease. The chapters on primary tuberculosis, on collapse therapy and on x-ray diagnosis have been considerably revised.

The book will be criticized by some because it is too brief in some sections, whereas in others it includes material that may be considered superfluous. But it makes no claim to completeness, and the best selection of material must inevitably be to some extent a matter of individual judgment. The reviewer believes that the essentials have been adequately presented. And they are presented from the point of view of physicians who have had many years' experience with the disease and with the human beings affected by it. Sound common sense and consideration of the patient as a whole are the dominant notes.

The significance of contact, especially between children and tuberculous adults, is emphasized in relation to the patient's history and to the prevention of tuberculosis. Pleurisy, especially with effusion, is pointed out as being frequently a tuberculous manifestation calling for prolonged bedrest like other forms of tuberculosis, and it is shown that the pulmonary form may often be prevented by the proper care of pleurisy.

There is a simple presentation of the pathology of pulmonary tuberculosis, with a discussion of the exudative and proliferative types. Primary or childhood infections are considered in their clinical, pathological and x-ray aspects, and again the importance of family contact is stressed.

Among the newer developments discussed are improvements in collapse therapy. These include pneumolysis as an aid to pneumothorax, the improved technic of thoracoplasty, the use of bilateral pneumothorax and the abandonment of phrenic operations except for a restricted group of cases. Other advances mentioned are the value of gastric lavage in diagnosis, the more restricted reliance placed on heliotherapy and climate, and the newer con-

ceptions concerning the desirability or undesirability of a positive tuberculin reaction. It is pointed out that a primary infection in an adult is no worse than in a child, and that although it may confer a very slight degree of immunity, it also brings a much greater risk of subsequent reinfection tuberculosis than if the tuberculin reaction had remained negative.

The book is very simply written, and there is a brief summary at the end of each chapter. Also with each chapter are selected references to the literature. The illustrations are clear, and the x-ray photographs well reproduced. An index is included.

The Surgery of the Alimentary Tract. By Sir Hugh Devine, M.S., F.R.A.C.S., F.A.C.S. 8°, cloth, with 690 illustrations, some in color. Baltimore: Williams and Wilkins Company, 1940. \$15.00.

One of the common criticisms of surgical volumes is that they are largely compilations, that they are written by men who have the time in which to write but not the experience from which to draw. Such a criticism certainly cannot be made of this volume. It is outstandingly an individual's book, based on personal views and personal experience. It proposes to be that and refreshingly makes no effort to be anything else.

The work deals with but a limited number of surgical subjects, those particularly in which the author has been interested. It presents the views of a man busy in the practice of surgical diagnosis and surgical therapy. Dr. Devine has contributed many original and practical procedures to surgery, and the deductions by a person with such a large experience and with such an original mind are always of great interest and benefit to surgeons similarly occupied. The book is pre-eminently suited for those who have had considerable experience in surgery, but may be read with profit by those whose interests are surgical but who have not as yet had a large experience in it.

Physiology of Micturition: Experimental and clinical studies with suggestions as to diagnosis and treatment. By Orthello R. Langworthy, M.D., Lawrence C. Kolb, M.D., and Lloyd G. Lewis, M.D. 8°, cloth, 232 pp., with 49 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$3.50.

This publication adds greatly to our present understanding of normal and abnormal functions of the urinary bladder. It contains the results of many experimental and clinical observations made during a period of seven years in the laboratories of the Johns Hopkins University School of Medicine and in the wards of the Johns Hopkins Hospital. For the first time the correlation between the complicated nerve supply of the bladder and its behavior in various forms of neurologic disease has been put on a logical basis. The literature on this subject, heretofore conflicting, has been carefully evaluated.

The book comprises six sections. The first concerns the anatomy of the urinary apparatus and its nerve supply; the second and third discuss the pharmacology and physiology; the fourth treats abnormalities of urination in diseases of the peripheral nerves and spinal cord; the fifth considers these in diseases of the brain; and the final section presents a summary of clinical experience in diagnosis and treatment.

The book deserves high commendation and will undoubtedly be of special interest to both clinicians and urologists, as well as to teachers of physiology.

HERNIA AS THE PRESENTING COMPLAINT IN PATIENTS WITH CIRRHOSIS OF THE LIVER AND ASCITES*

MARK D. ALTSCHULE, MD†

BOSTON

THE fact that patients with cirrhosis of the liver and ascites may first consult their physicians because of a hernia of the abdominal wall has received but little attention in the medical literature. Similarly, the frequency of hernia has not been generally appreciated. Chapman, Snell and Rowntree,¹ in 112 cases of ascites due to cirrhosis, found hernias in over 40 per cent. Of particular interest were 2 patients in whom ascites was first discovered during the course of herniorrhaphies. Observations in this clinic have amply corroborated these authors' conclusions as to the high incidence of hernia in patients with cirrhosis and ascites, and I have been impressed by the not infrequent fact that such patients may first request surgical rather than medical advice.

CASE REPORTS

CASE 1 (B I H 3698) R. A., a 20-year-old American Jewish salesgirl, entered the hospital complaining of "a rupture in the navel." Eight months previously, following an upper respiratory infection, a small mass appeared at the umbilicus. Two months before admission, her physician advised operation. Two weeks before admission, the mass became purple in color. The patient had gained an undetermined amount of weight in the 6 months before entry. Physical examination revealed an everted umbilicus with a mass 2 by 4 cm protruding through it. The abdomen was large, but no signs of fluid were elicited, the liver and spleen were not palpable. Slight edema of the ankles was noted. The skin was sallow. The diagnosis of cirrhosis was not considered, and herniorrhaphy was performed the day after admission. During the operation about 2500 cc of fluid flowed from the incision, which was then extended, revealing a large congested spleen and a very small, hard, hobnail liver. After operation the patient was drowsy and complained of itching, but no definite jaundice was discernible for 3 or 4 days, after which the icterus index was 30 and the serum bilirubin 21 mg per 100 cc. The patient failed rapidly and died on the 5th postoperative day. Postmortem examination revealed portal cirrhosis and splenomegaly.

The diagnosis of cirrhosis of the liver was not entertained until an operation for umbilical hernia was performed, when the liver was examined because a large amount of fluid was unexpectedly encountered.

CASE 2 (B I H 45242) G. H., a 36-year-old American machinist with a history of chorea at the age of 9 and mild dyspnea on exertion at the age of 28, visited his physician because of a rapidly enlarging mass in the right inguinal region. This was diagnosed as an inguinal hernia, and herniorrhaphy was recommended. At the time of operation for repair of the hernia a "large amount of fluid" ran out of the incision. A year later, 5 years before his death, the patient's abdomen and legs swelled, and abdominal paracenteses were performed every 2 months. Dyspnea, formerly mild, became severer, and repeated hospitalization was necessary for the treatment of both the congestive failure and hepatic cirrhosis. He died at the age of 42, 6 years after operation for hernia first revealed the presence of severe liver disease. Postmortem examination showed portal cirrhosis with splenomegaly, the heart was the seat of rheumatic valvular disease involving the mitral, aortic and tricuspid valves.

This patient had rheumatic heart disease, and his first symptoms were referable to the heart. A rapidly enlarging inguinal hernia was operated on, and the presence of ascites was thereby revealed, this was the first indication of severe liver disease, for it was not until a year later that the physical signs of ascites appeared.

CASE 3 (B I H 46485) B. L., a 74-year-old Russian Jewish tailor, whose brother had died of disease of the liver, developed attacks of upper abdominal pain, with chills and intermittent fever, 6 years before admission to the hospital, and icterus 18 months before admission. At this time he was studied at another hospital, where a diagnosis of gall bladder disease was made, operation was not performed, however, because of the possibility of the presence of hepatitis. The patient then felt well for 1 year, but 5 months before admission noted a mass in the left inguinal region. He came to the Out Patient Department, where he was given a truss. Five months later the abdomen and legs swelled, and he was accordingly admitted to the medical ward. Examination at this time revealed marked icterus, a large amount of ascites, an enlarged liver, a large

*From the Medical Service, Beth Israel Hospital and the Department of Medicine, Harvard Medical School.

†Instructor in Medicine, Harvard Medical School; associate visiting physician and research associate, Beth Israel Hospital.

left indirect inguinal hernia and marked edema of the legs. The patient was transferred to the Surgical Service, and a choledochostomy was performed. Many liters of ascitic fluid were removed during the operation. The liver was nodular and deeply bile stained, and the common bile duct contained many stones. The patient failed to improve after operation and died several days later. Post-mortem examination revealed acute and chronic cholangitis and biliary cirrhosis.

This patient with known disease of the gall bladder developed a large inguinal hernia five months before signs of ascites appeared. The presence of hepatitis had been suspected earlier as a result of the occurrence of chills and fever together with the onset of icterus. Nevertheless the development of the hernia was not regarded as an integral part of the pathologic process, that is, as an indication of ascites due to biliary cirrhosis secondary to gall-bladder disease.

CASE 4 (B. I. H. 50239). S. M., a 53-year-old Latvian-Jewish painter, came to the Out-Patient Department complaining of a swelling in the right inguinal region that he had first noted 1 year previously. For some time he had been aware of the increasing prominence of his abdomen. He also had complained of chronic cough, pains in the arms and legs, deafness, tremor, dizziness, weakness, insomnia, headache, nosebleeds, dyspnea, anorexia and swelling of the ankles. He was admitted to the medical ward, where anemia, slight icterus, ascites and splenomegaly suggested the diagnosis of hepatic cirrhosis; this was confirmed by peritoneoscopy. He lived for several months, during which repeated abdominal paracenteses were performed, and finally died in coma. Post-mortem examination was not performed.

The development of a large inguinal hernia caused this patient to come to the hospital, where the diagnosis of cirrhosis of the liver with ascites was established.

In addition to the cases described above, 3 patients have been observed in this clinic in whom hernias, which had appeared together with the

onset of ascites, later caused alarming new symptoms as a result of incarceration. In 2 cases, operations were withheld because of the poor condition of the patients; both recovered after a stormy illness. The third patient was operated on successfully.

COMMENT

The incidence of hernia is high in patients with hepatic cirrhosis and ascites, and at times symptoms referable to the hernia itself may first cause the patient to seek medical attention. Thus in the 4 cases reported above, the development of a hernia was the first indication of severe intra-hepatic disease, or at least of ascites; in 2 the ascites was discovered only during herniorrhaphy. Abdominal hernias have further significance in the life history of hepatic cirrhosis, since the not infrequent occurrence of incarceration creates a grave emergency in these patients.

It is unlikely that ascites in itself causes the development of hernia, for hernias were found in less than half the patients with large amounts of abdominal fluid studied by Chapman, Snell and Rowntree,¹ as well as in those observed here. Hernias previously present as latent defects probably enlarge as a result of the long-standing increase in intra-abdominal pressure due to the presence of ascites. Large amounts of abdominal fluid have the same significance in this regard as chronic cough.

The purpose of this communication is to call attention to the advisability of considering the diagnosis of hepatic disease with ascites in patients complaining of hernia.

PRIMARY ADENOCARCINOMA OF THE JEJUNUM*

ERNEST L. HUNT, MD,[†] AND GEORGE D. KANEH, MD[‡]

WORCESTER, MASSACHUSETTS

IN the literature, references to primary adenocarcinoma of the jejunum are rather scarce, conforming to the low incidence of the disease in this portion of the bowel as compared with carcinoma of other parts of the gastrointestinal tract. Because of this infrequency, surgeons are less familiar with the lesion than with carcinoma at the more usual sites. Ewing,¹ in the recent edition of his book, devoted to this subject approximately one page of text and one illustration. "Marshall,"² in his excellent work on chronic diseases of the abdomen, dismisses the subject with one sentence, "Cancer of the small intestine constitutes 1 per cent of bowel cancers; it presents the classic ladder-pattern obstruction with empty cecum and occult blood in the feces." Mayo and Nettrour,³ from the largest series of cases from any single source found carcinoma of the small intestine to constitute but 0.47 per cent and of the jejunum 0.15 per cent of all carcinomas of the gastrointestinal tract.

Although the jejunum thus seems to be relatively immune from cancer, the patient is particularly unfortunate when it does occur. The impression is general, and supported by the experience of many, that treatment is usually unsatisfactory. Thus Mayo and Nettrour³ in the paper referred to above conclude with the words, "The operative mortality of carcinoma of the jejunum is 20 per cent, while the average duration of life is 17.6 months following operation." This opinion is supported by Medinger's⁴ analysis of 22 cases from Boston sources, of which 19 were treated by operation, with a mortality of 47 per cent, "of the survivals, 3 patients are living and well with no recurrence for periods of eleven years, three years and less than one year."

For the purpose of this paper we have considered 3 cases, 1 of which was treated jointly by the writers, and 2 by other members of the staff of the Worcester City Hospital. A review of the hospital records from 1921 to 1938 inclusive, during which 81,447 patients were admitted to the surgical department, reveals that 28,135 surgical specimens were examined in the laboratory, of which only 3 were reported as carcinoma of the

jejunum. In the same period 2266 autopsies were done; carcinomas of the gastrointestinal tract were found in 67, but none of these were primary in the jejunum. There were also 147 operative cases of histologically verified gastrointestinal carcinoma, of which 3, or 2.1 per cent, were of the jejunum.

Because our small experience seems to justify a slightly more optimistic attitude toward these lesions, and because we believe that by focusing the attention of clinicians on the condition improved results may follow its more reasonable recognition, we venture to report the following cases.

CASE REPORTS

CASE 1. G. M., a 58-year-old draftsman, was admitted to the Surgical Service, Worcester City Hospital, on March 14, 1928, complaining of constant dull epigastric pain of four months' duration, radiating to the right costal margin, at other times shooting posteriorly to the right scapula. Vomiting, not infrequently late at night or in early morning, produced a watery, greenish material sometimes exceeding the immediate fluid intake. Concurrently the patient lost 25 pounds. There was no history of jaundice, constipation or coffee grounds vomitus, but he stated that he had had 'indigestion' for a number of years.

Physical examination revealed a well developed and fairly well nourished, rational man, in no acute distress, who had a temperature of 99°F. The head, neck, ears, nose, throat, lymph nodes and chest were normal. The blood pressure was 105/85, the pulse was 104, and regular in rate and rhythm. The abdomen was tense, and the stomach distended with gas and fluid. The liver descended 1 cm. below the right costal margin and was slightly tender to palpation. There was an old healed right inguinal herniorrhaphy scar.

Examination of the blood showed a red cell count of 5,300,000 with a hemoglobin of 70 per cent, and a white cell count of 12,000. No blood serologic findings were recorded. The specific gravity of the urine was 1.025, it was acid, and no sugar or albumin was present.

On March 16, 1928, with the patient under ether anesthesia, Dr. Marsh operated and found an enormously distended stomach and duodenum. About 7 cm. distal to the duodenojejunal junction, a constricting growth was encountered. No nodules were felt in the liver or in the mesentery of the small bowel. The section bearing the neoplasm was resected, and the bowel continuity restored by an end-to-end anastomosis. The patient made an uneventful recovery and was discharged from the hospital on the 19th postoperative day.

The pathological report at the time was 'adenocarcinoma.' Although the gross specimen is no longer available the slides are on file and have recently been reviewed by Drs. Raymond H. Goodale and Shields Warren, who concur in the diagnosis.

†Consulting surgeon, Worcester City Hospital, surgeon in chief, Fairbairn Hospital.

‡Graduate assistant, Medical Outpatient Department, Worcester City Hospital.

The patient is now alive, 12 years after operation.

CASE 2.* A 52-year-old Italian laborer was admitted to the Surgical Service, Worcester City Hospital, on February 6, 1933, complaining of the belching of gas and of constipation of 3 days' duration. He was well until 4 months before entry, when he was seized by a severe epigastric pain, which later settled about his umbilicus. This was followed by nausea and several bouts of vomiting. As the pain slowly abated he noted a great deal of gurgling of the bowels. Following this episode the pain had persisted more or less; he had been unable to eat solid foods, and his appetite had gradually waned. Constipation insidiously increased, so that just previous to admission he had experienced one movement every 3 or 4 days. There had been no hematemesis, melena, jaundice or clay-colored stools. The weight had remained remarkably constant. The past and family histories were noncontributory.

Physical examination revealed a well-developed and well-nourished man in no distress. The temperature and respirations were normal. The blood pressure was 156/76. The pulse was 88, regular in rate and rhythm. The abdomen was distended, especially in the lower half. There was no spasm, rigidity, tenderness or palpable masses. Borborygmi were definitely auscultable.

Examination of the blood showed a white-cell count of 12,200, and a red-cell count of 5,100,000 with a hemoglobin of 80 per cent (Tallqvist). The urine was dark in color, with a specific gravity of 1.023 and no sugar or albumin. The blood Wassermann and Kahn tests were negative. The blood alkali reserve was 60.2 vol. per cent, the sugar 80 mg. per 100 cc., the nonprotein nitrogen 35.3 mg., the icteric index 12, and the van den Bergh test negative.

The x-ray report was as follows: "The stomach and duodenum are normal. At 6 hours the stomach is empty, the head of the meal is at the hepatic flexure. The jejunum shows several much-dilated coils. At 24 hours the dilated jejunum is still prominent. Diagnosis: obstruction of small intestine; etiology uncertain (adhesions?)."

On February 10, under ether anesthesia, Dr. A. W. Boyden opened the abdomen and encountered a distended jejunum. A hard constricting mass about the size of an ordinary hen's egg, indented on the mesenteric side, was found and resected with about 15 cm. of the intestine. An end-to-end anastomosis was performed, and the wound closed. Recovery was smooth, and the patient was discharged on the 21st hospital day.

The resected portion, when split, showed a hard mass intruding into the lumen of the intestine and occluding it except for a space on the antimesenteric side barely sufficient to admit the tip of the little finger.

The pathological report was as follows: "Gross examination shows a piece of intestine measuring 10 cm. in length containing a polypoid tumor mass measuring 3 by 2.5 by 3 cm., and a second tumor mass at the same level measuring 2.5 by 3 by 2 cm. The surfaces of these tumors are made up of small papillary projections. Sections reveal adenocarcinoma of the jejunum of low malignancy."

The patient has been followed and is now, 7½ years later, working full time at his usual employment.

CASE 3. A 76-year-old Syrian priest was first seen professionally by one of us (E. L. H.) on September 8, 1936, because he had discovered a lump in his abdomen. For

years he had suffered from indigestion, for which he had taken bicarbonate of soda with more or less relief. He was an inveterate smoker of cigarettes, was rather abstemious in diet, and used alcohol sparingly. About 3 weeks before seeking advice he had been seized by a sharp epigastric pain while celebrating Mass. This eased somewhat in 15 minutes but persisted for 8 to 10 hours and left him weakened for 2 or 3 days. Examination of the abdomen revealed a lax and thin abdominal wall with a visible prominence at the left of the navel. A well-defined ovoid mass, seemingly the size of a lemon, could be readily felt, and was freely movable, slipping under the hand like a floating kidney. It was nontender, and there was no evidence of gas-pocketing near it. No blood had been observed in the stools.

The patient was referred for x-ray study of the colon, with a tentative diagnosis of cyst of the mesentery. The report was as follows:

A flat film of the abdomen taken before injection of the barium shows the kidney outlines fairly well on both sides. They appear normal in position and outline. A soft-tissue mass is visible just below the shadow of the left kidney, which corresponds to the area of the mass in the abdomen.

There is no delay in the filling of the colon, and no definite filling defects are noticed. The mass in the left lower quadrant can be moved independently of the colon. There is no sign of intrinsic disease of the colon.

On the chance that this might represent a mass in the stomach, a small drink of barium was administered, but the stomach also is entirely separate from the mass. The course of the barium could not be followed down through the small intestine because of the fairly large amount of barium retained in the colon following evacuation.

The following week, again while celebrating Mass, the patient was overcome by another attack of epigastric pain, which persisted until the next day. He entered the Worcester City Hospital on September 27, where physical examination revealed a well-developed, fairly well-nourished aged white man in no acute distress. There were a few crackling rales at the lung bases. The heart sounds were of fair quality and regular in rate and rhythm; a soft systolic murmur was heard over the aortic area. The blood pressure was 128/80. The white-cell count was 16,700, and the red-cell count 4,120,000 with a hemoglobin of 85 per cent. The urine showed a very slight trace of albumin and a trace of sugar. No serologic examination of the blood was made.

At operation on September 28 by one of us (E. L. H.) under spinal anesthesia, the abdomen was opened through an oblique incision on the left side. A large movable ovoid mass covered with adherent omentum was encountered and delivered into the wound. The omentum was divided, and the true character of the growth revealed. It was an ovoid mass 10 by 8 cm., involving a loop of jejunum in two places, with a loop about 30 cm. in length between the two attachments. There were numerous enlarged lymph nodes in the adjacent mesentery. No nodules could be felt in the liver. The intestine was divided between clamps about 15 cm. above and below the attachments of the growth, and resected with a correspondingly large section of the mesentery, including the enlarged lymph nodes. Repair was made by end-to-end anastomosis and suture of the mesentery. The incision was closed without drainage.

*Courtesy of Dr. Everett P. Jewett.

The pathological report by Dr. R. H. Goodale was as follows:

Gross examination shows 50 cm. of small intestine attached to a cystic mass 10 cm. in diameter (Fig. 1). The wall of the cyst measures 2 cm. in thickness. The center is filled with mucopurulent material. The intestine is adherent to the mass 10 cm. from the resected end. Near the other end there is a fistulous communication with the mass, at which point the intestine is flattened out over the surface of the cyst. The cyst wall is soft and cuts with ease.

Sections show islands of epithelial cells in a dense connective-tissue stroma (Fig. 2). The cells show moderate variation in size and staining quality.

loom large against the background of general clinical experience, early recognition and prompt and efficient treatment are of vital consequence to the patient. It should therefore be kept well in mind when one is confronted by a gastrointestinal problem.

The average of patients having this disease is stated by Ewing² as 46.5 years. In Rankin and Mayo's⁶ series of 55 cases, it was 47.5 years, whereas Mayo and Nettrour³ obtained an average of 51.0 years. Stein,⁶ in his group of 8 cases, reported an average of 47.5 years. Our 3 cases gave an

FIGURE 1. Case 3.

Photograph of gross specimen. A = dense constricting growth; B = narrowed lumen; C = softened area; D = area from which section was taken. (Photograph by M. D. Carrigan.)

There are numerous mitotic figures and definite gland formation.

Diagnosis: adenocarcinoma of jejunum (medium malignancy).

The postoperative course was uneventful except for a chill following an intravenous injection of glucose solution on the second day, and a small collection of serum in the upper end of the incision. The patient was discharged on the 14th day.

The patient remained at home for the most part. He had a chronic cough and lacked strength. His bowels functioned well, but his appetite remained poor. In March, 1938, he developed a severe persistent pain in the left thigh. It had the character of a referred pain, and x-ray films of the pelvis were taken but revealed no cause for the symptom. Later the femur showed apparent thickening, and x-ray films showed the shaft extensively involved (Fig. 3). X-ray therapy was administered without notable relief. The patient succumbed on January 27, 1939, of cachexia, 2 years and 4 months after operation.

Although carcinoma of the jejunum does not

average of 62 years, and all occurred in men. The literature shows a preponderance of men over women in a ratio of 2:1.

The malady bears no distinctive hallmark. Its manifestations and clinical course are influenced by the type of local growth, which may be polypoid, ulcerative, sclerosing, excentric or annular, or any combination of these characteristics. Symptoms of a general nature may be those first noticed by the patient, among which weakness and fatigability are most frequent, and may be associated with anemia of mild or considerable degree. Indigestion and anorexia are usually experienced and may be associated with weight loss. Fortunate is the patient whose doctor at this point is aware of the possibilities involved and insists on a complete diagnostic study. The presence of occult blood in the feces after exclusion of oxidase-contain-

ing foods indicates the strong probability of an organic lesion somewhere in the digestive tract.

"Indigestion" takes the form of intermittent cramps near or below the navel and is associated with rumblings and borborygmi, which may come such a considerable time after eating that the patient does not associate them with the taking of food. Constipation is usual, but lacks the alternation with diarrhea common to large-bowel tumors.

FIGURE 2. Case 3.

Low-power photograph of a section, showing the adenomatous structure and dense connective tissue. (Photograph by M. D. Carrigan.)

Vomiting depends on the degree of obstruction and the height of the lesion. It may be absent, slight or severe, and may occur intermittently in association with other manifestations of obstructive attacks. Salivation and frequent vomiting of copious amounts of fluid should at once suggest this lesion. Hemorrhage sufficient to be recognized as hematemesis or melena may occur, but commonly does not. Loss of weight and secondary anemia may be considerable. X-ray studies may reveal retardation of the passage of barium and dilatation of the jejunum (or duodenum) above the lesion; the dilated portion is identified as the jejunum by its deep circumferential folds (Kerkring's). Flat films for gas reveal the typical ladder pattern according to the degree and site of the obstruction. Physical examination shows gas-filled loops, with visible peristalsis accompanied by cramps and borborygmi. Palpable tumor, when present, is significant and usually slips about under pressure of the hand.

Episodes of acute obstruction with pain, distention and vomiting are commoner with the polypoid forms, which may also cause intussusception.

TREATMENT

All authorities agree that timely and adequate operation is the only means for approximating

a cure. Wide resection with re-establishment of continuity of bowel by end-to-end, side-to-side or end-to-side anastomosis is the object to be attained. When there is a combination of suggestive symptoms, such as intermittent pain, secondary anemia, distention and vomiting with the presence of occult blood in the stool, even if x-ray studies have failed to establish a diagnosis, exploration is justifiable. Hodgkins's⁷ advice to go at once to the areas most commonly the seat of cancers of the small intestine, namely, the upper jejunum and the lower ileum, is worth remembering, to minimize operative trauma.

Recent years have brought valuable contributions to the methods for dealing with intestinal obstruction from any cause. One should mention supportive measures directed toward restora-

FIGURE 3. Case 3.

Photograph of x-ray film, showing extensive metastatic involvement of the femur.

tion of physiologic requirements of tissue fluids, electrolytes, carbohydrates and blood-protein (transfusion) by the parenteral route. Decompression by Miller-Abbott or Wangenstein intubation methods has contributed much toward lowering mortality rates and supplanting enterostomy. Improved technics of resection, including the aseptic methods of Rankin and Mayo⁵ and others, lessen the dangers of the procedure. Since the majority of jejunal cancers lie near the proximal end of that bowel segment, the methods of duodenojejunal anastomosis devised by Rankin⁵ and by Lahey⁸ enlarge the possibilities of radical removal. The physical equipment and technical skill for

all these procedures are indispensable to success in dealing with the disease.

SUMMARY

Experience with three cases of carcinoma of the jejunum is presented.

There was no operative mortality.

There was postoperative survival without present evidence of disease of eleven years and eight years in two cases, whereas the third patient, an aged man, succumbed from metastatic lesions in two years and four months.

Hope for improvement in the results of treating this rare condition is based on the improved diag-

nostic, supportive and operative procedures now available.

TRICHINOSIS

Report of a Case, With Demonstration of the Larva in the Arterial Blood*

GUSTAVE J. DAMMIN, M.D.†

NEW YORK CITY

THE development of complex refinements in laboratory technic has been accompanied by a neglect of older, simpler and yet important methods of laboratory diagnosis. This has evidently occurred in trichinosis, since little mention is ever made of examination of the blood for the larva of *Trichinella spiralis*.

Isolation of the larva of *T. spiralis* from the human blood stream was first accomplished by Herrick and Janevay¹ in 1909. In their case, the larvae were recovered on the twenty-third and twenty-fifth days after the ingestion of infested pork. Their method consisted of laking venous blood with 15 volumes of 3 per cent acetic acid, centrifugalizing and examining the sediment.

Since the patient is usually seen when the symptoms are those that occur during the period of dissemination of the larvae,—puffiness of the eyelids, conjunctivitis, fever and muscle pains,—the laboratory diagnosis should be most readily established by isolating the *T. spiralis* larva from the blood stream. Usually at that time, the suspected meat is not available for examination, and it is too late to recover the dead adult male worms from the feces. Permission for muscle biopsy is not always obtainable, and when it is performed does not always contribute to the presumptive diagnosis.² With two possible exceptions, an early positive diagnosis of trichinosis cannot be made without demonstrating the larval or adult stage of the causative organism. These exceptions are

a positive precipitin test and a positive skin test. The precipitin titer may be elevated during the period of dissemination, a circumstance that occurred in the case to be presented. Precipitin titers rising during the course of illness and convalescence permit a positive diagnosis of trichinosis. Using the skin test, a positive diagnosis can be made only if an initial negative intradermal reaction is followed by a positive one, or if a delayed positive reaction is followed by an immediate positive one.³ An immediate positive skin test does not permit a positive diagnosis, since such a reaction has been shown to persist for at least three years after an attack of trichinosis.⁴ However, should the patient be seen early during the period of dissemination, neither of these tests may be positive. A clinically typical case during an epidemic and the presence of eosinophilia, although very suggestive, still permit only a presumptive diagnosis of trichinosis. Therefore, because of the time at which the patient is usually seen, and because of the usual train of immunologic events, isolation of the larva of *T. spiralis* offers the earliest means of making a positive diagnosis of trichinosis.

Since the literature on general and specific aspects of trichinosis has recently been admirably covered,^{2,4} no further review is warranted.

The following case is presented to illustrate the value of examination of the blood for the larva of *T. spiralis*, with a modification of the original procedure, namely, the use of arterial blood, and to call attention to an unusual but important find-

*From the Medical Clinic, Peter Bent Brigham Hospital.

†Assistant in pathology, Columbia University College of Physicians and Surgeons, formerly, assistant resident physician, Peter Bent Brigham Hospital.

ing, namely, the development of typhoid H and O agglutinins during the course of illness.

CASE REPORT

E. E. K. (P. B. B. H. No. 115298) was a 38-year-old German-born butler who entered the hospital on May 28, 1940, because of burning and puffiness of the eyes of 5 days' duration, together with fever and malaise of 2 days' duration. The patient had never had typhoid fever and he had never received prophylactic inoculations for that disease. He had had psoriasis, limited to the elbows and knees for as long as he could remember.

On May 7, 1940, and for several days thereafter, the patient was said to have partaken, with several other members of the household, of some imported smoked ham. Preparation of the ham before eating did not include heating in any manner. On May 23, 16 days after first ingestion of the smoked ham, the patient's initial symptoms appeared. He complained of low frontal headache, swelling of the upper eyelids, and redness and burning of the eyes. By the following day, the swelling of the upper lids had receded slightly, but swelling of the lower lids appeared. On May 25, the patient noted dizziness and malaise. The next day he felt too ill to rise. He was found to have an oral temperature of 100°F., and the same night he had a shaking chill. On May 27, the day before admission, the patient complained of severe aching pains in the gastrocnemius muscles. The palpebral edema had subsided somewhat.

That the patient's contact with trichinous meat occurred on May 7 is confirmed by the facts that three other members of the household developed symptoms of trichinosis—puffiness of the eyes, muscle pains and fever—on or after May 14 and that the patient had eaten no pork subsequent to May 9.

On admission to the hospital the patient appeared severely ill. The temperature was 103°F., and the pulse 96. The skin was hot and moist. Over the elbows and knees were the erythematous, silver, scaled lesions of psoriasis. There were no subungual splinter hemorrhages. Chemosis and marked injection of the bulbar conjunctivas were present; in the left fundus there was a small fresh hemorrhage. The tongue was reddened, and the tip was tender. The lungs were clear, and examination of the heart revealed no abnormalities other than an apical systolic murmur. The blood pressure was 124/80. There was no abdominal tenderness. In the left axilla, there were several enlarged, palpable lymph nodes. The forearms and lower legs were tender to palpation. Neurologic examination was negative.

The blood showed a white-cell count of 7300, with 15 per cent eosinophils; the red-cell count was 5,800,000, with a hemoglobin of 110 per cent (Sahli) and a hematocrit of 42 per cent. The sedimentation rate was distinctly elevated—34 mm. per hour (Wintrobe). The urine showed occasional erythrocytes in the sediment. The urine was examined for larvae, and the stools for the adult males, but *T. spiralis* could not be recovered in either form. The serum-phosphatase test showed a normal value of 3 Bodansky units per 100 cc. The blood Wassermann and Hinton tests were negative.

Since conjunctivitis, chemosis, palpebral edema, muscle pains and tenderness were present, the patient was considered to be in the stage of larval dissemination. On May 29, 5 cc. of venous blood was laked with 15 volumes of 3 per cent acetic acid, the specimen centrifugalized and the sediment examined. No larvae were

found. Because of their route of propagation the larvae were searched for in the capillary blood on the following day, with negative results. On May 30, 5 cc. of blood was removed from the brachial artery and prepared as described above, and from this preparation larvae of *T. spiralis* were recovered (Fig. 1).

The patient's course and laboratory studies are summarized in Figure 2. For 6 days after admission, the fever was of a high-grade, remittent type, and the temperature did not return to normal until the 11th hospital day. The palpebral edema was absent after the 4th, and the muscle aches subsided after the 5th hospital day.

A chest film taken on May 29 showed slight exaggeration of the lung markings but no localized involvement. An electrocardiogram taken on May 31 showed normal tracings. Muscle biopsy was not performed. Stool and urine cultures revealed no pathogenic bacteria. Skin tests, using the National Institute of Health trichina antigen in a 1:10,000 dilution, were performed on May 29, June 4 and July 10, with results as indicated in Figure 2.

FIGURE 1. Photomicrograph of the Migratory Form of the Larva of *Trichinella spiralis*.

A = anterior valved hyaline cap; B = oblique hyaline band (Stäubli?); C = leukocytes.

Trichina precipitin tests, performed at the National Institute of Health, showed the highest titer (1:1280) with serums of May 29 and June 4. The eosinophilia reached 45 per cent on June 2, and 1 month after discharge had fallen to 6 per cent. No agglutinins for typhoid H (formalin-killed) antigen or typhoid O antigen were present initially, but by July 10 agglutinins were present in serum dilutions of 1:640 and 1:1280, respectively. Serums obtained on four occasions were tested for proteus OX₁₀ agglutinins; the initial titer was low and remained essentially unchanged.

Examination of the arterial blood for the migratory larval form of *T. spiralis* provided a simple, rapid method for early laboratory diagnosis in this case. It also rendered unnecessary a muscle biopsy, which is more expensive and time consuming.

Because of a difference of opinion concerning the size and morphology of the migratory form of the larva of *T. spiralis*,^{5, 6} a detailed description is warranted at this time. One of the better descriptions is to be found in Stäubli's⁷ monograph. The migrating larva is said to measure 80 to 120 microns in length, and 6 microns in width. The

specimen shown in Figure 1 measured 115 by 5 microns. Anteriorly, a valved hyaline cap (*A*) is situated, and separating the anterior fourth from the posterior three fourths of the body, there is an oblique hyaline band (*B*).⁷ The remainder of the body is granular in appearance. These features are readily demonstrable with Wright's stain.

An unusual feature in this case was the development of agglutinins in high titer for typhoid *H* (formalin killed) and *O* antigens. It is sig-

nificant here because there was no antecedent history of typhoid fever, and because the patient had received no prophylactic typhoid inoculations. The presence of typhoid agglutinins in trichinosis was reported by Maase and Zondek⁸ in 1917. In 3 cases of trichinosis proved at autopsy, typhoid agglutinins were present in serum dilutions of 1:400, using a live antigen. There was no agglutination demonstrable, however, when a killed typhoid antigen was used. In none of the cases was there a history of typhoid fever or of prophylactic inoculation, nor were the lesions of typhoid fever demonstrable at autopsy. Conner⁹ reported 2 patients with trichinosis who developed typhoid agglutinins after recovery. In one of these, the presence of typhoid agglutinins was transient, in the other, repeated tests were positive—on one occasion in

a dilution of 1:2560. It is difficult to assess the significance of typhoid agglutinins in trichinosis, and further search for the presence of a common antigen is to be carried out.

Weil-Felix tests, using proteus OX₁₉, were performed because the clinical picture of trichinosis may resemble that of typhus or Rocky Mountain spotted fever, and because a positive reaction of no immediate significance might be detected, as the one that occurred with the typhoid agglutina-

FIGURE 2

nificant here because there was no antecedent history of typhoid fever, and because the patient had received no prophylactic typhoid inoculations. The presence of typhoid agglutinins in trichinosis was reported by Maase and Zondek⁸ in 1917. In 3 cases of trichinosis proved at autopsy, typhoid agglutinins were present in serum dilutions of 1:400, using a live antigen. There was no agglutination demonstrable, however, when a killed typhoid antigen was used. In none of the cases was there a history of typhoid fever or of prophylactic inoculation, nor were the lesions of typhoid fever demonstrable at autopsy. Conner⁹ reported 2 patients with trichinosis who developed typhoid agglutinins after recovery. In one of these, the presence of typhoid agglutinins was transient, in the other, repeated tests were positive—on one occasion in

trichinosis. However, agglutination occurred in no serum dilution higher than 1:40, which titer can be found in 21 per cent of routine serums.¹⁰

Another unusual feature in this case was the presence, relatively late in the course of illness, of a delayed positive skin reaction, which was followed by two negative reactions, the latter of the two tests being performed with as much as 0.1 cc of the National Institute of Health trichina antigen (1:10,000). This is at variance with the findings of Spink,³ who noted that delayed positive skin reactions were invariably followed by immediate positive reactions.

SUMMARY

A case of trichinosis is presented in which the larva of *Trichinella spiralis* was recovered from

arterial blood after unsuccessful examination of venous and capillary blood. The examination of arterial blood is suggested as a modification of the original technic of Herrick and Janeway.¹

Because of the simplicity of the method and its value in early laboratory diagnosis of trichinosis, examination of arterial blood is considered a useful procedure.

During the course of observation, agglutinins to typhoid H (formalin-killed) antigen and typhoid O antigen developed from initial titers of zero to agglutinations in serum dilutions of 1:640 and 1:1280, respectively.

The initial skin reaction to National Institute of Health trichina antigen (1:10,000) was of the delayed positive type. This was followed by two

negative reactions, the latter of which was performed two months after exposure.

CLINICAL NOTE

THE VALUE OF VITAMIN K IN THE TREATMENT OF ABNORMAL BLEEDING*

RICHARD CHUTE, M.D.†

BOSTON

IN THE last year or two so much attention has been drawn to the subject of prothrombin deficiency and therapy with vitamin K in cases of abnormal bleeding that the presentation of such a case occurring in urologic practice seems timely.

CASE REPORT

A 21-year-old man entered the hospital because of repeated attacks of pain in the right kidney region accompanied by hematuria. X-ray examination showed a stone, the size of a lima bean, in the kidney at the ureteropelvic junction. The past history revealed nothing abnormal. The patient had always been healthy. He had undergone tonsillectomy uneventfully 9 years before. He had never had any abnormal bleeding, nor was there any family history of such bleeding. Physical examination revealed a healthy-appearing young man. Neither spleen nor liver was palpable, nor were there any abnormal lymph nodes. The blood-cell counts and smear were not abnormal. A blood Hinton test was negative. The only abnormal finding was a systolic blood pressure of 150, which was probably due to preoperative excitement, since the diastolic pressure was only 70. Pyelolithotomy under ether anesthesia was carried out uneventfully. A small incision was made in a good-sized extrarenal pelvis, and the stone was easily removed. The incision in the pelvis was sutured loosely with two stitches, and the wound was closed in the usual manner, with drainage. At no time was the parenchyma of the kidney wounded. The immediate convalescence was very satisfactory, with no abnormal bleeding.

By the 4th postoperative day, the temperature was down

to normal, the wound was draining only a little urine, and that voided was fairly clear. On the 5th and 6th postoperative days the patient began to run a slight evening fever and to have some blood in the urine. On the 7th day the temperature suddenly went up to 103°F., the pulse to 125, and the urine began to be grossly bloody, with long wormlike clots, apparently casts of the ureter. Simultaneously, bleeding began from the wound, good-sized clots coming out through the drainage sinus. Thus it appeared that there was bleeding not only from the interior of the kidney into the urine, but also from outside the kidney. Since by this time the urine had stopped leaking out through the wound, and since there was thus apparently no connection between the inside of the kidney and the wound, it was extremely puzzling to imagine what could cause bleeding from both inside and outside the kidney, especially since the parenchyma of the kidney had not been wounded at operation. For the next 4 days moderately profuse bleeding continued both in the urine and from the wound. On the chance that there was some abnormality of the bleeding or clotting mechanism, studies of these were made, and it was found that, whereas, the bleeding time was normal (2½ minutes), the clotting time in five tubes was 27 minutes in the first three and 39 minutes in the others. This abnormality was definite evidence of prothrombin deficiency. Unfortunately—because it was Saturday—a prothrombin determination could not be done that evening. The patient was immediately given a blood transfusion and 6000 Almquist units of vitamin K by mouth. By the next morning, both the intrarenal and extrarenal bleeding had decreased somewhat, and the pulse and temperature, which had been elevated ever since the bleeding had started, had gone down almost to normal. By Monday morning—36 hours later—the clotting time was approaching normal—7 minutes in the first tube and 13 minutes in the others; the prothrombin time was essentially normal, being 18 seconds (normal, 19 seconds). By the next day the clotting time was 6 minutes in the first tube and 11 minutes in the others. During the course of the next few days the patient received 2000 units of vitamin K by mouth daily, and the intrarenal and extrarenal bleeding gradually ceased. When he left the hospital on the 26th postoperative day, the urine contained only a rare red blood cell, and the wound was draining only a very small amount of clear serum.

*Presented at a meeting of the New England Section of the American Urological Association, Boston, May 2, 1940.

†Assistant in genitourinary surgery, Harvard Medical School; assistant urologist, Massachusetts General Hospital.

One thinks of reduction of prothrombin with abnormal bleeding as occurring especially in cases with jaundice and liver damage, and in such conditions as cirrhosis of the liver, the cachexia of cancer, chronic loss of blood, peptic ulcer, chronic sepsis, malnutrition and avitaminosis. However, this patient was a vigorous appearing young man, apparently enjoying the best of health, except for the attacks of pain and hematuria due to the kidney stone. He had not been jaundiced and gave no history of abnormal bleeding. Therefore, the discovery of this condition was a complete surprise, and made me wonder if I had in the past occasionally encountered cases of abnormal bleeding similarly due to prothrombin deficiency that

I had failed to recognize as such. In retrospect, a few patients who bled longer and more persistently than normal may well have been deficient in prothrombin. In such operations as nephrolithotomy, prostatectomy and even transurethral prostatic resection, the surgeon cannot ligate all the bleeding points and must of necessity depend a good deal on the natural blood-clotting mechanism of the body. Therefore I believe that this subject is of particular interest to urologic surgeons, especially because the introduction of prothrombin determinations and vitamin K therapy has made diagnosis and treatment simple and satisfactory.

352 Marlboro Street

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Stated Meeting, February 5, 1941

A STATED meeting of the Council of the Massachusetts Medical Society was held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, February 5. The meeting was called to order at 10:30 a.m. by the president, Dr. Walter G. Phippen, Essex South, 209 councilors were present (Appendix No. 1).

The Secretary *pro tempore* presented the record of the meeting of the Council of October 2, 1940, as published in the *New England Journal of Medicine*, issue of October 31. Following a vote, the President declared the record approved as published.

The following obituary of a councilor who had died since the last meeting was read by the President:

DR. EDWARD MELLUS, of Newton, died December 7, in his sixty-ninth year.

Born in Zumbrota, Minnesota, he attended Harvard College, and received his degree from the Harvard Medical School in 1903. He was a member of the Newton Board of Health, a member of the staff of the Newton Hospital, a former member of the Newton City Planning Board, and a member of the New England Society of Psychiatry. At the time of his death he was treasurer of the Middlesex South District Medical Society.

Dr. Mellus maintained a sanatorium in Newton until 1929, when he retired from active practice.

Two sons and a daughter survive him.

The Council stood in silent tribute to the memory of Dr. Mellus.

The report of the Auditing Committee (Appendix No. 2), signed by Drs. Edwin B. Dunphy and Henry W. Hudson, Jr., was read by the treasurer,

Dr. Charles S. Butler. It was voted to accept the report as presented.

The report of the Treasurer (Appendix No. 3) was presented by him and was duly accepted.

REPORTS OF STANDING COMMITTEES

Membership

The chairman, Dr. G. Colket Caner, Suffolk, presented the report (Appendix No. 4), which was accepted. The first six items, recommending that sixteen fellows be allowed to retire, one fellow be nominated for affiliate fellowship in the American Medical Association, twelve fellows be allowed to resign, six fellows be allowed to have their dues remitted, forty-eight fellows be deprived of fellowship because of nonpayment of dues and six fellows be allowed to change their districts without change of legal residence, were approved. The seventh item, recommending that the dues of fellows called to active service in the United States Army, Navy or Public Health Service be remitted, subject to certain limitations, was accepted.

Financial Planning and Budget

The report (Appendix No. 5) was presented by the chairman, Dr. John Homans, Suffolk. It consisted of the recommendations for the budget for 1941, and copies had already been distributed to all councilors. Dr. Homans explained that the amounts specified for the Executive Assistant, Executive Secretary and Secretary were suggestions, since the status of these officers depended

on subsequent action by the Council; however, the total amount recommended was adequate to cover any contingency. Following a short discussion, the budget was approved.

Ethics and Discipline

The chairman, Dr. Robert L. DeNormandie, presented the report (Appendix No. 6). Dr. David Cheever, Suffolk, commented on the committee's request for advice in regard to whether the committee should give more publicity to the complaints brought before it. The lack of further discussion was tacit approval of the committee's policy in handling these matters. The report and recommendation were accepted.

Medical Education and Diplomas

The first part of the report (Appendix No. 7) was presented by the chairman, Dr. John P. Monks, Suffolk. Dr. Monks stated that he preferred to have the recommendations considered in two parts—the first having to do with the application for fellowship of graduates of unapproved and foreign medical schools, and the second with the reapplication for fellowship of members who had resigned at the request of the Committee on Ethics and Discipline. Dr. Reginald Fitz, Suffolk, suggested that the matter should be deferred until the Council was better informed in regard to the recommended changes.

In a general discussion that followed, the question whether the proposed changes in the by-laws had been properly presented to the Council was argued. The President ruled that they had not "been submitted previously in writing to the Council," and hence that no action could be taken. It was eventually moved by Dr. Cheever that a special meeting of the Council be called for the specific business of considering these matters after the circulation of additional information. The motion was seconded and passed.

Dr. Monks then read the second part of the report, and the President ruled that these recommended changes in the by-laws should also be considered at the special meeting.

State and National Legislation

The chairman, Dr. Henry C. Marble, Suffolk, presented the report (Appendix No. 8). A motion to accept the report was made and seconded, and the matter opened for discussion.

Dr. Michael A. Tighe, Middlesex North, commented on the charge by the Board of Registration in Medicine that the Society had done nothing to improve the archaic medical practice act, adding that it was largely through the efforts of the Society and its officers, rather than those of the Board, that the so-called "Educational Bill," which

created the Approving Authority, was passed in 1936. Dr. Tighe stated that the limiting date of the act had already been postponed for two years and that now a bill has been filed to postpone once again the effective date. The latter was confirmed by Dr. Marble.

Dr. Brainard F. Conley, Middlesex South, said that the Society had always been ready to cooperate with the Board, but that it had never been asked to do so. When the Society offered to help the Board to obtain adequate funds, he added, this help was refused and the bill for annual registration followed. Dr. Conley stated that, in his opinion, any committee or commission to investigate surgery should be appointed by the Society rather than by the Legislature and the Governor. And he corroborated Dr. Tighe's statement to the effect that the passage of the Approving Authority Bill was chiefly owing to the efforts of the Society and its president, Dr. Charles E. Mongan.

Dr. Tighe questioned Dr. Marble as to the attitude of the Board to the bill postponing the effective date of the Approving Authority. Dr. Marble replied that he did not know.

The President asked for a vote of acceptance of the report of the committee; it was so voted.

The first recommendation—the appointment of a committee by the President to investigate the practice of medicine in the Commonwealth—was duly adopted.

After some discussion, no motion was made to adopt the second recommendation,—the appointment of a committee by the President to consider the practice of surgery and the matter of restricted licensure,—and the President declared the matter dropped.

Dr. Tighe moved that the committee be instructed to oppose Bill 611, which would permit extension of the effective date of the Approving Authority. The motion was seconded and duly passed.

No reports were made by the Committee of Arrangements, the Committee on Publications, the Committee on Public Health, the Committee on Medical Defense and the Committee on Permanent Home.

REPORTS OF SPECIAL COMMITTEES

Cancer

The chairman, Dr. Shields Warren, Suffolk, presented the report (Appendix No. 9), which was accepted.

Public Relations

The report (Appendix No. 10) was presented by the secretary, Dr. Elmer S. Bagnall, Essex

North, who moved its acceptance, which was duly seconded. Dr. James H. Townsend, Middlesex South, asked for an explanation of the essential points of difference between the enabling act sponsored by the Society and the bill proposed by the supporters of Health Service, Incorporated. At the request of the President, Dr. Thomas H. Lanman, Suffolk, chairman of the special committee to promote a medical costs insurance plan, replied that there were only two essential points of difference: first, the Society's bill permits the participation of all physicians licensed to practice, whereas the other bill limits the qualifications of participating physicians, and, secondly, the Society's bill places control under the supervision of the Commissioner of Insurance, whereas the other bill designates the Commissioner of Public Health as the supervising agent. The report was accepted.

Postgraduate Instruction

The report (Appendix No. 11) was presented by the chairman, Dr. Frank R. Ober, Suffolk. The report and the two recommendations were accepted.

Industrial Health

The report (Appendix No. 12) was read by the Secretary *pro tempore* and was accepted.

Army Medical Library and Museum

The report (Appendix No. 13) was read by the Secretary *pro tempore* and was accepted.

At 1:05 the President declared a recess, during which the Cotting Luncheon was served. The Council reconvened at 1:45 p.m.

Examination of WPA Records

The chairman, Dr. Guy L. Richardson, presented the report (Appendix No. 14), which was accepted.

To Consider New Officers and By-Laws

The chairman, Dr. Homans, referred to the report of the committee (Appendix No. 15), which was published in the January 16 issue of the *Journal* and copies of which had been forwarded to each councilor. He requested that the report be considered in two parts: first, that dealing with the offices of president-elect and executive secretary and, second, that concerning other suggested changes. Dr. Homans then explained in some detail the duties of the proposed executive secretary, and added that the matter of president-elect was probably less controversial.

Dr. David L. Lionberger, Norfolk, commented on the committee's admission, in regard to the second part of the report, that the committee was not representative. Since, in his opinion, the mat-

ter of redistricting the Society is of utmost importance and since the first part of the report is more or less dependent on the second, he offered the following motion:

That the committee report be accepted as one of progress and that the committee be kept intact, and that the entire matter with any additional change in the by-laws be vested with an enlarged committee made up of one representative elected by each district society, and that this committee report at or before the next meeting of the Council.

In continuing the discussion, Dr. Cheever made two suggestions: first, that no office of president-elect be created but that, when referring to the office of vice president, the phrase, "who shall serve as president-elect," be added, and secondly, that certain minor changes in verbiage be made to obviate the necessity for appointing an executive secretary but still permitting such an appointment if it seemed desirable. Dr. Monks stated that he believed the phrase, "the executive secretary need not be a fellow of the Society, should be changed to read, "the executive secretary need not be a physician." Another councilor said that he did not believe the executive committee, proposed in the second part of the report, was truly representative of the Council and that each district society should have a member.

Dr. Butler raised an objection to Dr. Cheever's suggestion of electing the vice president and president-elect in one. He said that the vice president was usually elected because of some outstanding contribution to the Society and that he was not necessarily the one to carry on as president.

Dr. Donald Munro, Suffolk, questioned the advisability of appointing the executive secretary for only one year, since, in his opinion, such an arrangement was distinctly against the probability of obtaining a competent man.

Dr. Norman A. Welch, Norfolk, agreed that the proposed executive committee was not truly representative, and said that he was in favor of Dr. Lionberger's motion, particularly in view of the problem of redistricting.

Another councilor stated that the provision to appoint a fellow to the executive committee for three years raised a complication, since councilors are elected for only one year.

On questioning by the President, Dr. Lionberger repeated his previous statement, namely, that all matters in the report should be considered and reported to the Council by an enlarged committee. After further discussion, Dr. J. H. Blaisdell moved to amend Dr. Lionberger's motion by striking out the words following report of progress

The President then asked the vice-president, Dr. Ober, to take the chair. Dr. Phippen outlined the various advantages to be derived from the proposed offices of president-elect and executive secretary and from an executive committee. He added that redistricting of the Society was a matter that required considered and time-consuming deliberation, whereas the other matters might be advantageously decided at the moment. Dr. Blaisdell agreed with this suggestion and said that that was the reason for his proposed amendment, whereas Dr. Lionberger still maintained that all these matters were inter-related. Dr. Blaisdell's motion of amendment was seconded. At this point the President resumed the chair.

After considerable discussion as to parliamentary procedure, Dr. Blaisdell's motion—to the effect that the report be accepted as one of progress—was put and carried. Dr. Lionberger immediately offered the remainder of his original motion. Dr. George D. Henderson, Hampden, in the absence of a seconding of the previous motion, moved that the creation of the offices of president-elect and executive secretary be considered; this motion was seconded and passed. It was then moved, seconded and voted that the Council approve in principle the election of a president-elect and of an executive secretary.

Dr. Cheever then moved that subsequently elected vice-presidents be designated "president-elect," to succeed at the next following annual meeting. This motion was seconded; it was supported by Drs. Henderson and Edward F. Timmins, Suffolk, and opposed by Drs. Halbert G. Stetson, Franklin, and Peirce H. Leavitt, Plymouth. It was not carried.

Dr. Homans then moved the acceptance of the by-laws relating to the creation of the office of president-elect; the motion was seconded and carried. He then moved that the creation of the office of executive secretary be accepted in principle and that the necessary changes in the by-laws be submitted at the next (special) meeting of the Council. This motion was seconded and carried.

Dr. Charles E. Mongan, Middlesex South, asked for the privilege of moving that an enrollment be taken of the councilors present; he said that this was occasioned by his belief that every councilor should arrange his affairs to be able to stay throughout the meeting. The motion was accepted by the President, seconded and carried. (The Secretary *pro tempore* subsequently distributed papers for enrollment [Appendix No. 16].)

Dr. Tighe called attention to the fact that the matter of the creation of an executive committee was still in the hands of Dr. Homans's committee and that it was the sense of the meeting that each

district society should be represented on such a committee by one member.

Restoration to Fellowship

Ten restorations to fellowship (Appendix No. 17) were authorized by the Council.

New committees to consider restoration for four fellows (Appendix No. 18) were nominated by the President and approved by the Council.

APPOINTMENT OF DELEGATES

The President nominated the following delegates and alternates to the House of Delegates of the American Medical Association:

<i>Delegates</i>	<i>Alternates</i>
John M. Birnie, Hampden	Robert J. Carpenter, Berkshire
Richard H. Miller, Suffolk	Cadis Phipps, Norfolk

It was voted to close the nominations and to declare those nominated as duly elected.

The President then nominated the following fellows as delegates to the annual meetings of the medical societies of the other New England states:

Maine: Edwin D. Reynolds, Essex South, and Stuart N. Gardner, Essex South

New Hampshire: Joseph C. Merriam, Middlesex South, Frank W. Snow, Essex North

Vermont: Ira M. Dixon, Berkshire, and Stanley A. Wilson, Essex South

Rhode Island: Ralph W. French, Bristol South, and Benjamin H. Alton, Worcester

Connecticut: George L. Schadt, Hampden, and George L. Steele, Hampden

The Council confirmed the nominations.

On motion of the President, Dr. Reginald Fitz, Suffolk, was voted delegate to the Annual Congress on Medical Education and Licensure of the American Medical Association, to be held in Chicago on February 17 and 18.

CONFIRMATION OF APPOINTMENTS

The *ad interim* appointment of Dr. John G. Downing, Middlesex South, as councilor was approved.

INCIDENTAL BUSINESS

Dr. DeNormandie read a motion proposed by Dr. Louis E. Phaneuf, Suffolk, namely:

I move that the President appoint a committee of ten doctors to be distributed geographically throughout the State, including at least two pediatricians; said committee to be called a Committee on Maternal

Welfare, with power to deal with all matters pertaining to maternal welfare in the State of Massachusetts

Dr DeNormandie explained that the executive committee of the Section of Obstetrics and Gynecology was a more or less self appointed body, and that the Society should have, as do many of the state medical societies, an officially recognized and appointed committee to act on state and national problems of maternal welfare. The motion was seconded and passed.

Dr Conley, representing Dr Marble, the chairman, moved that the Committee on State and National Legislation be authorized to oppose the three bills presented by the Massachusetts Board of Registration in Medicine. The motion was seconded and passed.

The President then brought up the question of having a new, small sized plate engraved for diplomas of membership, stating that although such a change seemed wise, the officers hesitated to make a change without authority. A motion by Dr Homans to empower the officers of the Society to select a new diploma was seconded and carried.

The Secretary *pro tempore* read a letter from Dr Herbert Margolis, of the Oral Hygiene Council of Massachusetts (Appendix No 19). This was referred to the Committee on Public Health.

Dr Homans remarked that he was a bit uncertain about the duty of the committee appointed to consider changes in the by laws. Dr Tighe placed his former suggestions in the form of a motion that the committee continue and that it explore the possibilities of an executive committee so constituted that each district medical society would be represented. This was seconded and passed.

Dr Daniel J. Ellison, Middlesex North, related experiences with licensed, nonmember, refugee physicians who requested endorsement from the local medical society so that they could obtain hospital privileges. Little or nothing was known about the men, and their requests were denied. The district medical society voted to request the Council to take action on the recommendation that all physicians who are licensed to practice medicine in Massachusetts shall be full citizens of the United States. The motion was seconded and, after considerable discussion, was referred to the committee authorized to investigate the practice of medicine in the Commonwealth.

The meeting adjourned at 3 45 p m

ROBERT N. Nye, *Secretary pro tempore*

The Auditing Committee:

Dr. Edwin B. Dunphy
Dr. Henry W. Hudson, Jr.

The Massachusetts Medical Society

8 Fenway
Boston, Massachusetts

Gentlemen:

At the request of your treasurer, Dr. Charles S. Butler, we have examined the books and accounts of the Massachusetts Medical Society for the twelve months ended December 31, 1940, and submit herewith:

SCHEDULE A: Statement showing the balance sheet of the Massachusetts Medical Society, December 31, 1940.

SCHEDULE B: Statement showing the revenue and expenses of the Massachusetts Medical Society for the twelve months ended December 31, 1940.

The cash balance at December 31, 1940, was verified by direct correspondence and reconciliation. The cash receipts as recorded have been properly accounted for, and disbursements are supported by vouchers or canceled checks.

The securities and savings bank books in the various funds were examined and found to be as shown in this report.

The accompanying balance sheet and related statement of revenue and expenses fairly present the position of the Massachusetts Medical Society at December 31, 1940, and the results of operations for the year ended on that date.

Respectfully submitted,
HARTSHORN AND WALTER.

50 Congress Street
Boston

APPENDIX NO. 3

REPORT OF THE TREASURER

During the year 1940 a number of bonds, owned by the Society and carrying coupons of 4 per cent or more, have been called for early payment. In consequence, the Treasurer has replaced them, in part, by good quality bonds, but with lower interest rates. The result has been to reduce income and also to oblige the Society to maintain an unreasonably large cash balance. As you know, conditions of low-interest returns have existed for several years past, until now, industrial and other prime AA and AAA bonds, even with coupon rates of 2 or 2½ per cent, sell at premiums. The U. S. Treasury is borrowing hundreds of millions of dollars, from time to time, at no cost in interest; in fact, the lenders, in most instances, are paying premiums to the Government to accept their loans. The Treasurer carries in mind, at all times, three impelling considerations: one, the threat of dangerous inflation; secondly, the influence of heavy and heavier federal and state taxation, imposed by present world-wide conditions; and thirdly, the protection of the invested principal of the Society's funds, disregard of, largely, considerations of income.

Revenues, in 1940, from resident dues were \$49,871, showing an increase over 1939. Nonresident dues were \$1569; so that combined annual dues were \$51,440, the largest amount ever received by the Society from this source. Other revenues—from invested funds: \$3647, from sales, \$38; from profits on securities sold, \$652; and from booths at annual meeting \$709—together amount to \$3046. During the year, all interest due (other than on three issues long years in default) and coupons have been promptly paid to the Society. Hence, the total combined revenue in 1940, not including that of the Building Fund, was \$56,487, again the largest amount ever received by the Society.

The Building Fund received income of \$1905 and a small profit from securities sold. Both were added to the Fund, which now amounts to over \$60,000.

Regarding expenses, the Treasurer calls attention to the salary of the editor emeritus of the *Journal*. In previous years he had given generously to the Society. In the past year he would not accept his salary, preferring that the Society should keep it; the Treasurer argued with him, but failed to convince him. Another expense, that of the Committee on State and National Legislation, was \$3200 less in 1940, owing to the fact that the Legislature was not in session.

The Society ends 1940 with total assets of cash and securities of over \$204,000, showing an increase during the year of about \$13,000.

The Treasurer is glad to thank the officers of the Society, the district treasurers, the office staff of the *New England Journal of Medicine* and, in particular, his secretary for their loyalty and help.

The Treasurer invites questions and will be glad to try to answer them.

CHARLES S. BUTLER, Treasurer.

APPENDIX NO. 4

REPORT OF THE COMMITTEE ON MEMBERSHIP

The committee recommends:

1. That the following named sixteen fellows be al-

lowed to retire as of December 31, 1940, under the provisions of Chapter I, Section 5, of the by-laws:

Cousens, Nicholas W., Waltham, with remission of dues for 1938, 1939 and 1940
 Dickson, Richard E., Holyoke
 Drummey, Nicholas D., Dorchester
 Gray, Hugh B., Boston
 Hayden, Louis B., Livermore Falls, Maine
 Hurwitz, Abraham J., Boston
 Kazanjian, Hampar P., Los Angeles, California, with remission of dues for 1939 and 1940
 Lally, Francis H., Milford
 Lawler, William P., Lowell
 Lec, Wesley T., Boston
 Mandell, Augustus H., New Bedford
 Noyes, Nathaniel K., Plymouth
 Rice, George B., Boston
 Sawyer, Walter F., Fitchburg, with remission of dues for 1938, 1939 and 1940
 Watts, Henry F. R., Dorchester
 Woods, Charles E., Lunenburg

2. That the following named fellow be recommended for affiliate fellowship in the American Medical Association:

Drummey, Nicholas D., Dorchester

3. That the following named twelve fellows be allowed to resign as of December 31, 1940, under the provisions of Chapter I, Section 7, of the by-laws:

Barrett, Joseph E., Marion, Virginia
 Carbone, Joseph A., Gary, Indiana
 Cohen, Louis H., Norwich, Connecticut, with remission of dues for 1940
 Ehrenclo, Alfred H., New York City
 Hartshorne, Isaac, New York City
 Holt, Charles H., Pawtucket, Rhode Island
 Lewis, Frank E., Nantucket
 Patterson, George W., South Ryegate, Vermont, with remission of dues for 1940
 Price, Noble H., Lamesa, Texas, with remission of dues for 1940
 Reid, William D., Boston
 Reuter, Robert J., Milwaukee, Wisconsin
 Watson, James, Raleigh, North Carolina

4. That the dues of the following named six fellows be remitted under the provisions of Chapter I, Section 6, of the by-laws:

Booth, Ernest L., East Boston, 1941
 Flagg, H. Howard, Charlestown, 1941
 Lawlor, Edward F., Jr., Lawrence, 1938 and 1939
 Moore, Carleton W., Liberia, Africa, 1938 and 1939
 Philbrick, Roscoe H., Coconut Grove, Florida, 1941
 Ruel, Joseph A., Bradford, 1938 and 1939

5. That the following named forty-eight fellows be deprived of the privileges of fellowship under the provisions of Chapter I, Section 8, Clauses *a* and *b* of the by-laws:

Appel, Bernard H., Brighton
 Bailey, Karl R., Jamaica Plain
 Bell, Robert M., St. Louis, Missouri
 Buck, Clifton L., Danvers
 Burnett, Nathan L., Cambridge
 Cabeceiras, Henry J., Belmont
 Canzanelli, Pericles, Watertown

Chayet, Jacob, West Roxbury
 Ciani, A. Walter, Iowa City, Iowa
 Cohen, Harold I., Lynn
 Cregg, Francis A., Methuen
 Cruff, Frederick E., Norwell
 Cummings, Vincent P., North Adams
 Curtin, John F., North Abington
 DeWolfe, Henry M., Braintree
 Dushan, Sidney S., Dorchester
 Ford, Leroy S., Keene, New Hampshire
 Gazzaniga, Dante A., Los Angeles, California
 Gerstein, Maurice, Brookline
 Gilbert, Meyer M., Lynn
 Halbach, Robert M., Jamestown, Rhode Island
 Hannigen, Robert C., Amesbury
 Kudish, Benedict, West Upton
 LaRochelle, Arthur H., Chicopee Falls
 Larsen, Carl J., Orlando, Florida
 Lewis, Robert B., Fort McKinley, Maine
 Liverpool, Coval H., Somerville
 Lynn, Sherwood C., Savannah, Georgia
 McEvoy, George A., Chestnut Hill
 Merrill, Wiggin L., Plymouth
 Mikolaitis, Casimir J., Lawrence
 Milward, Frank W., Cleveland, Ohio
 O'Toole, John L., Haverhill
 Paine, Mortimer H., South Hanson
 Petit, Alphonse H., Ware
 Pulsifer, Nathan, Lowell
 Reese, Lewis L., Waban
 Regan, Timothy F., Lawrence
 Rooney, John F., Worcester
 Rosen, Leonard B., Lynn
 Sannella, Theodore, Revere
 Silver, Maurice J., Dorchester
 Silverman, Nathan, Lawrence
 Stearns, Robert T., Greenbush
 Tynan, James L., East Milton
 Udelson, Barnet A., Roxbury
 Uniac, Thomas V., Lawrence
 Vartanian, Mardiros B., Lawrence

6. That the following named six fellows be allowed to change their membership from one district society to another without change of legal residence, under the provisions of Chapter III, Section 3, of the by-laws:

From Middlesex South to Suffolk
 Colby, Fletcher H., Newton Centre
 From Norfolk to Middlesex South
 Wood, Harold, Jamaica Plain

From Norfolk to Plymouth
 Wheatley, Frank E., Milton

From Norfolk to Suffolk
 Frothingham, Joseph R., Brookline
 Keefer, Chester S., Brookline
 Kunkel, Paul, Brookline

7. That the Council provide for the remission of dues of fellows who are called to full-time service in the United States Army, Navy or Public Health Service, as follows:

Fellows of the Society who are called to full-time service in the United States Army, Navy or Public Health Service during the present emergency and whose livelihood is thereby impaired may, on written application to the Treasurer stating their situation,

have their dues remitted for the year of service. A period of full time service greater than six months shall give the privilege of a year's remission of dues. The *New England Journal of Medicine* will be sent to such members only on payment of an annual fee of four dollars (\$4.00). The president of the Society shall determine the end of the present emergency.

G COLFET CANNON *Chairman*

APPENDIX NO 5

REPORT OF COMMITTEE ON FINANCIAL PLANNING AND BUDGET

The following appropriations are recommended for 1941

Salaries	
Executive Assistant (night June 1)	\$534
Executive Secretary (after June 1)	2100
Secretary	14 0
Until June 1	\$ 50
After June 1	00
Treasurer	9000
Expenses of Officers and Delegates	
President and Vice President	500
Secretary	1500
Treasurer	450
Director treasurers	2 00
Censors	900
Delegates to House of Delegates American Medical Association	800
Maintenance of Society Headquarters	4500
Shack Lecture	200
Cutting Luncheons	450
Standing Committees	
Arrangements	1000
Films and Discipline	150
Financial Planning and Budget	10
Medical Defense	2000
Medical Education and Medical Diplomas	0
Membership	10

Special Committees	
Industrial Health	50
Postgraduate Instruction	1000
Public Relations	1000
Section of Obstetrics and Gynecology	150
Returns to District Societies	4000
	\$51 879

APPENDIX NO 6

REPORT OF THE COMMITTEE ON ETHICS AND DISCIPLINE

Since our last report to the Council, the Committee on Ethics and Discipline has held four meetings.

The greatest number of complaints that are received are because of unethical advertising. Fellows against whom such complaints have been made have had letters from the committee asking for an explanation, pointing out the committee's stand and asking them to desist from such methods.

Three complaints have been received because of allegedly exorbitant fees charged by fellows. In one case, after careful investigation, the committee thought the fee reasonable and so wrote the complainant. Our letter straightened out the entire matter, and the complainant has again consulted the fellow for aid in his difficulties.

The other two cases are at present before the courts, and no comment is advisable.

Two fellows have been connected with the procuring of abortions. The resignation of one of these fellows has been accepted by the Council, and the other case is still under consideration by the committee.

There is little or no publicity of the complaints that are brought before us. The committee has many times talked over the advisability of making reports to the Council more specific, even to the extent of mentioning names of those who have proved themselves unworthy of fellowship in the Society.

The committee has attempted by friendly discussion to show fellows who have been called before it wherein the members thought they had erred. Many times these friendly hearings have cleared up difficult situations. Frequently, however, the complaint is serious, the charge definite and the fellow deserves criticism. In such cases we often ask the president of the Society to reprimand the fellow.

The bylaws of the Society give us two other grades of punishment. We can in serious misconduct ask for the fellow's resignation or for a Board of Trial. Fortunately we have not recently considered it necessary to request the latter.

The committee frequently hears that it is not severe enough in dealing with certain cases that so long as there is no publicity no real good comes of its efforts. We cannot agree to this entirely for in some cases we are confident that appearance of fellows before the committee and frank criticism of their action accomplish the purpose. It is only in cases of gross misconduct that the question of greater publicity arises.

The committee welcomes discussion and advice from the Council on this difficult subject.

The committee recommends that the Council favor the change in the bylaws suggested by the Committee on Medical Education and Diplomas.

ROBERT L. DeNORMANDIE *Chairman*

APPENDIX NO 7

REPORT OF THE COMMITTEE ON MEDICAL EDUCATION AND MEDICAL DIPLOMAS

For several years among the applicants for fellowship in the Society the number of graduates of medical institutions not on the list recognized by the Council has been increasing. At the present there are two groups of such graduates. One, and much the larger group, is composed chiefly of graduates of domestic institutions not recognized as medical schools by the American Medical Association. This group also includes a few American born graduates of foreign medical schools who have studied abroad usually because they were not accepted by any recognized domestic medical school. There are a few foreign born foreign educated physicians in this group who migrated to this country, chiefly before 1937. The other group much smaller than the first, is composed almost entirely of foreign born graduates of foreign medical schools who are chiefly German and Jewish but by no means exclusively either. Most of these physicians have migrated recently to this country, primarily to escape political oppression. Almost without exception they have had a good medical education and are of proved ability often being older men of outstanding ability with international reputations.

The members of the Committee on Medical Education and Medical Diplomas are unanimous in believing

that it is in the best interests of the Society to treat these two groups differently. The basis of this difference we believe should be whether or not an applicant has had an adequate medical education and enjoys a good professional reputation. With very few exceptions the members of the first group have had an inadequate education, those of the second an adequate one, and it is usually not difficult to distinguish between them. We believe members of the first group should be admitted to membership only when there is ample positive proof that they can be regarded as truly desirable additions to the Society. At present in the absence of other evidences of undesirability besides an inadequate medical education, they are assumed to be desirable. We cannot agree with this attitude. We believe that the members of the second group should become members of the Society as soon as they have been long enough in this country to have created definite favorable opinion in the minds of colleagues whose judgment would be commonly considered valuable.

The committee has been unable under the present system to evaluate truly the desirability for fellowship of the majority of candidates appearing before it. Repeated attempts to gather information about the prospective candidates from the officers and fellows of the district societies have usually failed. A typical situation is for an applicant who is a graduate of an unrecognized domestic school to appear before the members of the committee; they have never seen him before, but must decide as to his desirability from his appearance, diploma, application blank and a sheaf of letters personally solicited from his medical acquaintances, who invariably say that the applicant "is a capable and conscientious practitioner of medicine" and that his practice is "ethical." Only rarely has the committee received what it regards as a confidential expression of honest intelligent opinion regarding an applicant and his work from colleagues who really know him. Part of the present functioning of the committee as dictated by the by-laws has become farcical in the minds of its members. A major change in this undesirable situation seems impossible under the present by-laws.

The committee therefore recommends that the following changes be made in the by-laws:

The name of the committee be changed to the Committee on Medical Education.

Chapter I, Section 1: In line 5 on page 9, delete the clause, "that their names and addresses . . . prior to their examination by the censors." In line 10 on page 9, omit the words "or college." In line 14 on page 9, after "code of ethics of this Society," insert "that they have made application according to the provisions of chapter V, section 2; that they have paid the examination fee of three dollars."

Chapter I, Section 6: In line 5 on page 10, substitute the word, "December," for "November."

Chapter V, Section 1: Beginning at line 11 from bottom of page 16, delete whole paragraph, "Diploma from medical schools . . . to take an examination."

In line 2 from bottom of page 16 substitute the word, "December," for "November."

At the bottom of page 16 insert the following: "A fee of three dollars shall be paid by an applicant for fellowship to the district secretary for deposit in the funds of the general Society before each examination or re-examination by the censors. An applicant shall not be considered as possessing the requisite qualifications for fellowship unless approved by at least three censors. An applicant failing two examinations

shall be disqualified from again applying for fellowship until three years have elapsed from the date of the last application."

Chapter V, Section 2: Change to read as follows: "An applicant for fellowship who is a graduate of a medical school recognized by the Council shall apply on a form furnished for the purpose to the secretary of the district in which he has legal residence, not later than March 1 for the May censors' examination or October 1 for the December censors' examination. At this time the district secretary shall verify the applicant's diploma and shall deliver the application form to the secretary of the Society not later than March 10 or October 10 respectively. An applicant nonresident in Massachusetts shall apply to the secretary of the Suffolk District Medical Society and shall be examined by the censors thereof. Consideration of a late application shall be postponed until before the next succeeding examination. The names of all such applicants, their addresses, medical schools and dates of graduation, and the names and addresses of the various district secretaries shall be published in a list in the first number of the *New England Journal of Medicine* on or after April 1 or November 1. Confidential communications regarding the qualifications of applicants for fellowship shall be requested of the fellows of the Society to be sent to the appropriate district secretary not later than April 15 or November 15.

"An applicant for fellowship who is a graduate of a foreign medical school or a domestic medical school not on the list recognized by the Council or of a medical school no longer in existence, and who has practiced for a minimum of five years, shall apply for fellowship in like manner with the following exceptions and additions:

"The application form must be submitted to the district secretary not later than February 15 or September 15. At this time also the applicant must submit the name and address of a fellow of the Society who has agreed to act as his sponsor. The sponsor's duty is to obtain from fellows of the Society, who are acquainted with the applicant and his work, confidential written opinions regarding his qualifications for fellowship to be mailed directly to the district secretary not later than March 15 or October 15. The application form of such an applicant shall be delivered by the district secretary to the secretary of the Society not later than February 20 or September 20. A list, similar to that of applicants who are graduates of recognized schools, but with the addition of names and addresses of sponsors, shall be published in the first number of the *New England Journal of Medicine* on or after March 5 or October 5.

"The president, secretary and supervising censor of the district society, sitting as a local board of membership, shall then gather such further information as is deemed necessary to determine whether an applicant is a capable and conscientious practitioner of medicine and possesses a good professional reputation among his colleagues. Every candidate must be personally interviewed by this board.

"The district secretary shall deliver to the chairman of the Committee on Medical Education a complete confidential file of all applications, including correspondence and written recommendations of the local board with supporting reasons for advocating the acceptance or refusal of each applicant not later than

April 1 or November 1. The committee shall then determine whether or not each candidate shall be approved for examination by the censors and shall notify the district secretary and each applicant of their decision not later than April 20 or November 20.

Chapter V, Section 3 In line 4 on page 17 after the words "applicants for fellowship insert clause they shall see that each applicant pays the examination fee."

Chapter VII, Section 5 Change the first two paragraphs to read as follows

The Committee on Medical Education shall consist of five fellows. It shall consider all matters relating to medical education which may be referred to it by the Council. It shall review the case of every applicant for fellowship who presents according to the provisions of chapter V, section 2, a diploma from a medical school not on the list recognized by the Council. It shall have the power to approve for examination by the censors such an applicant, and all decisions of the committee thereon shall be final. It shall revise the list of medical schools and colleges recognized by the Council whenever it appears necessary.

A recent ruling by the President reversed the previous interpretation of the provisions of the bylaws regarding the application for readmission to the Society of a former fellow whose resignation had been requested by the Committee on Ethics and Discipline. Inasmuch as the person in question was a graduate of an unrecognized school, it was ruled that he had to appear before the Committee on Medical Education and Medical Diplomas for approval, before being allowed to appear before the censors. Owing to information requested from the chairman of the Committee on Ethics and Discipline, the Committee on Medical Education and Medical Diplomas disapproved the application. The latter committee, as a result of this case, felt that it should have no jurisdiction in such cases of readmission to the Society, and as a result studied the provisions of the bylaws regarding readmission. With the approval of the Committee on Ethics and Discipline and the Committee on Membership it recommends that the following changes be made in the bylaws:

Chapter I, Section 7 Change to read as follows

The resignation of fellows whose assessments have been paid in full or remitted, may, on recommendation of the Committee on Membership, be accepted by the Council. Petitions to be allowed to resign should be addressed to the Council and sent to the treasurer of the Society.

Chapter I, Section 8 Omit last paragraph, "Fellows who have been deprived Secretary of the general Society."

To Chapter I add Section 10, to read as follows

"Former fellows who desire to be readmitted to the Society shall make application in writing addressed to the Council and sent to the secretary of the Society. Such applications shall be referred for investigation and personal interview to the local boards of membership, which shall report their recommendations to the Committee on Membership. The Committee on Membership shall render the final decision as to whether to recommend to the Council the readmission of former fellows. The Council shall have power to readmit former fellows so recommended. Boards having under consideration the applications of fellows whose resignations have been requested by the Committee on Ethics and Discipline or who have

been deprived of fellowship under the terms of Section 8, clause (c), shall consult with the Committee on Ethics and Discipline before reporting their recommendations.

JOHN P. MONKS, *Chairman*

APPENDIX NO 8

REPORT OF THE COMMITTEE ON STATE AND NATIONAL LEGISLATION

The Committee on State and National Legislation will report its activities chronologically beginning early in the fall of 1940.

After organization, we met with the State Board of Registration in Medicine, at their request, to discuss the proposed legislation. It was then that the committee was told that, in the past, the Massachusetts Medical Society had not been co-operative. Your committee, however, expressed a willingness and anxiety to co-operate and work together.

The legislation proposed by the Board was as follows: A bill for the annual registration of physicians, a bill requiring town clerks to report the registration of physicians and impose a penalty on physicians for failure to register with the town clerk, and a bill calling for a special commission to investigate the advisability of requiring special qualifications for physicians engaged in the practice of surgery.

In the discussion of the bill for annual registration, the difficulties under which the Board is working were taken up, and the inadequacy of the examination that is given to prospective candidates was illustrated. The large number of candidates and the lack of time make it possible to give a very limited written examination. The following is quoted from the report of Dr. Knowlton reprinted from the *Proceedings of the Annual Congress on Medical Education and Licensure* (Chicago, February 15 and 16, 1937):

The result is that the examinations are hodgepodge and a smattering of this and that subject with equal evaluation of each. In an examination given last fall, there were 220 applicants, about 90 came from approved schools and the remainder from nonapproved institutions. One examiner passed 156 of these applicants, with many high marks, another passed only 38, with just 6 or 8 ranging higher than 80 per cent. The general average passed by the other board members was 83 of the 220 applicants. Our problems in medical licensure in Massachusetts, therefore, are due almost solely to an out-of-date and clumsy medical practice act. It could be probably entirely rewritten if the state medical society would show real interest in changing it. There seems, however, no such interest. Instead, there seems to be an apathy bordering on an aversion of the society to do anything that will raise or improve the standard of practice in Massachusetts by changing the medical practice act. The backing of the society is absolutely essential before any real good can be accomplished.

It further appeared that on the day of our conference the Board had examined 100 alien physicians and had given each a personal interview. All the rest of the candidates had had only a written test. There was no oral or practical examination.

Upon further discussion of the matter of annual regis-

tration, we made it clear that based on the Dutton report (*New England Journal of Medicine* 222:393-396, 1940), we did not believe that it was advisable to push annual registration at this time, and we did not believe it would serve any useful purpose. The Board, however, reiterated to us the necessity for a larger budget, and we offered to them the proposal that if this legislation was not pressed we, as a committee, would go before the Budget Commissioner and ask for an adequate budget for the Board with which to carry out its work.

In regard to the second proposal, a bill requiring town clerks to report the registration of physicians and impose a penalty on physicians for failure to register with the town clerks, your committee agreed to approve this bill and promised to support it.

Relative to the third proposal, calling for a special commission to investigate the advisability of requiring special qualifications for physicians engaged in the practice of surgery, your committee took the stand that this should be an educational matter and strongly urged that it be referred to the Massachusetts Medical Society for thorough study, including the whole problem of restrictive licensure. We, therefore, promised that a resolve would be presented to the Council.

In spite of this agreement, all these bills were introduced. The Board reported that there had been a misunderstanding. Nevertheless, your committee feels bound to carry out its part of the bargain. We continued our request for an opportunity to go before the Budget Commissioner, and it was not until January 23, 1941, that we received a letter stating:

At the meeting of the Board of Registration in Medicine held January 9, 1941, your letter of January 8, 1941, was presented and the matter of the amount requested in the budget was considered. It was the sense of the Board that while a greater increase in the budget might be required later this year, the request for \$4097.50 for general expense is reasonable compared with actual expenditures.

In other words, despite repeated statements that the Board has not enough money to investigate and prosecute, they do not now require further funds. So far as we have been able to ascertain, the Board of Registration in Medicine has been given by the Budget Commissioner the amounts requested annually.

It is the considered opinion of this committee that the Board of Registration in Medicine is not giving adequate examinations (see Dr. Knowlton's report); that annual registration is unnecessary (see Dr. Dutton's report); that the practice of surgery in the Commonwealth would be best studied by a committee or commission of the Massachusetts Medical Society; and that the Board of Registration in Medicine does not now require more funds with which to carry on its work.

Following this, various legislative bills were studied, and we have attempted to keep up to date as they have been introduced. In general, these cover the bills introduced by the State Department of Public Health, bills requiring certain premarital examinations, a bill requiring an all-nurse board of registration, the osteopathic bill and the chiropractor bill. However, all these bills have been late in printing and at the present date, many of them are not in our hands. As soon as we can obtain these bills, a legislative bulletin will be made up and transmitted to the various members of the Society.

In each district a legislative committee has been appointed. They can be of tremendous value to us, and it is to them that we shall furnish the material relative

to legislative matters. We shall be appreciative of their support, and suggestions and recommendations are requested.

We present the following recommendations:

That a committee be appointed by the President to investigate the whole matter of admission to practice medicine in the Commonwealth.

That a second committee be appointed by the President to consider the matter of the practice of surgery, and also the matter of restrictive licensure.

HENRY C. MARBLE, *Chairman*.

APPENDIX NO. 9

REPORT OF THE COMMITTEE ON CANCER

The chief work of the Committee on Cancer during the past year has been aiding in the preparation and distribution of the book, *Cancer: A manual for practitioners*, a copy of which was sent to the address of every physician licensed to practice in the State. This book has been planned to aid the physician by giving him generally accepted facts about different phases of neoplastic disease, by giving him a clear picture of what is done by the State and by the national government in the field of cancer control and cancer research, and by giving him as well a source of material from which he may draw when called upon to address lay organizations on the subject of cancer. The committee realizes that in work of this type imperfections are inherent. Nonetheless, it believes that through the whole-hearted co-operation of a large group of men a succinct body of knowledge has been made available.

The various aspects of the cancer-control program of the State are continuing along the lines outlined by agreement with this committee. The committee believes that much of the success of this program, widely recognized as outstanding, has been due to the vision of the Department of Public Health and to the guidance of Dr. Herbert L. Lombard, the director of the Division of Adult Hygiene.

SHIELDS WARREN, *Chairman*.

APPENDIX NO. 10

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The committee presents the following report for your information and endorsement:

1. Dr. N. W. Faxon, representing the Blue Cross, invited our consideration of a project for the inclusion of individual subscribers—at slightly higher rates and after physical examination—in the plan for prepaid hospital care. The plan was approved in principle, and the committee after discussing several alternatives recommended that the Blue Cross select the panel of examining physicians. Other conditions of participation by physicians will be decided after further conference. The plan will not be initiated for several months.

2. A subcommittee of the Committee on Public Relations conferred with Drs. Huber and T. Duckett Jones, representing the Department of Public Health on January 15, 1941, in relation to the program for rheumatic heart disease. It was agreed that the plan should be operated at its inception in Boston, Worcester and Spring-

field and that only patients residing in the immediate vicinity of these centers should be admitted to its care. It was further agreed that the project would be extended only after conference and agreement between the Department of Public Health and the district medical societies.

Dr Huber favors a plan to have the family physician compensated for the first diagnostic visit and for follow-up visits after the patient is discharged from the hospital. He also recommends that the district society have a standing committee appointed to represent the interests of the physician in the selection of patients and so forth. As an indication of the prevalence of this condition it was found in a Connecticut survey that about 5 per cent of the school children were afflicted and 50 per cent of these were unrecognized.

The Department of Public Welfare at the State House has since the last Council meeting appointed as its medical adviser, under special statute—Dr B W Mandelstam. Dr Mandelstam has energetically proceeded toward an understanding of the problems involved in the administration of medical care to welfare and old age recipients.

Dr Mandelstam is making a survey of the three hundred and fifty-one communities in the Commonwealth. Approximately 38 per cent have furnished medical care on a contract basis and the other 62 per cent are allowed free choice of physicians under one plan or another. The free choice is usually allowed in the smaller communities. Several plans now in operation supply adequate medical care to the indigent and at the same time allow reasonable remuneration to the physician. Such plans have been more successful when the local medical group assumes intelligent initiative in the solution of these problems. It is obvious that no single plan would be feasible on a state-wide basis. The committee will stimulate the district committees on public relations to take the initiative in each of their several localities, consulting with the local welfare administrators with the view to improvement of existing conditions.

The Department of Public Welfare has selected a representative advisory committee of physicians to assist in the formulation of policies which will meet for the first time this evening. Our committee anticipates that this advisory committee may well carry on the work which inspired the appointment of this special committee by the Council.

The committee carefully considered with the Lanman committee and its legal advisers the enabling legislation for medical costs insurance.

We agreed upon and endorsed a bill for introduction into the Legislature. This bill has been filed at the State House and published in the *New England Journal of Medicine* and a copy has been mailed to each councilor. The officers of the committee met jointly with the Lanman committee and the Committee on State and National Legislation and agreed on the several responsibilities for advancing this bill toward enactment.

Because it has been reported that the White Cross representatives were creating the impression that they had tried unsuccessfully to meet our representatives for discussion of enabling legislation looking toward agreement and because editorials appeared in the daily papers indicating that the public interest would be served by agreement, the President after joint conference with the Lanman committee, the Committee on State and National Legislation and the Committee on Public Relations was authorized to arrange a conference if it was desired by the White Cross. The President thereupon arranged a

meeting for January 31, at the Tavern Club, to see if there could be agreement on a joint bill which might be substituted for the two bills on file. At this conference it was suggested that a compromise bill might be drawn up, and two representatives from each group were chosen—Drs Lanman and Tighe for the Massachusetts Medical Society and Mr Russell and Dr Frothingham for the White Cross. Thereupon Mr Twomey, our legal counsel, burned the midnight oil and prepared a joint bill for discussion by these conferees on February 2. At this meeting no agreement was reached but our conferees called a meeting of the Committee on Public Relations on the following day.

On February 3 a combined meeting of the Lanman committee, the Committee on State and National Legislation and the Committee on Public Relations was held at which the joint bill drawn up by Mr Twomey for the conferees was presented without recommendation or prejudice by Dr Tighe, vice-chairman of the Committee on Public Relations. Several hours were consumed in discussion, and it was eventually unanimously voted that support of the bill of the Society be reaffirmed with the following changes in the reading:

Section 3 be amended to read and not less than one third of the directors shall be persons who are or who agree to become subscribers to the Massachusetts Medical Society plan. (This is to be added at the end of the first sentence. The amendment was added because the bill does not specifically provide subscriber representation on the Board of Directors.)

Sections 1 and 7 to be amended to read: "medical service instead of general or special medical care." (This change was made in order that groups such as osteopaths or physicians not members of the Massachusetts Medical Society might not be disturbed by the original terminology, which could be interpreted as discriminating against them.)

These amendments are to be introduced with the Committee on Insurance whenever our responsible representatives consider it prudent.

The committee believes that this legislation is in the public interest. It was drawn up by the Lanman committee and its legal counsel after careful study of all the plans now operating in the United States under medical society sponsorship.

ELMER S. BARNALL, Secretary

APPENDIX NO 11

REPORT OF THE COMMITTEE ON POSTGRADUATE INSTRUCTION

This is the fourth year that the Society has given postgraduate extension courses, in co-operation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau, to all the physicians in the Commonwealth. The courses were started on October 22, 1940 and have been given in the following places:

DISTRICT	PLACE
Barnstable	Hyannis
Bristol North	Taunton
Bristol South	New Bedford
Essex North	Lawrence
Essex South	Salem
Middlesex East	Melrose

Middlesex North	Lowell
Middlesex South	Cambridge
Norfolk	Norwood
Norfolk South	Quincy
Plymouth	Brockton
Suffolk	Boston

The rest of the State will have similar courses this spring. A final report on the extension courses will be made at the annual meeting.

As reported at the October meeting, the committee has been instrumental in inaugurating a postgraduate extension library service, which has just begun to operate. This is a new service which the committee hopes will be useful to physicians, particularly to those who do not have nearby library facilities. Reference books and periodicals at present are related to the current postgraduate extension courses. Eventually this list may cover all major fields of medicine. All reference material will be delivered free to physicians who apply. State and federal agencies are aiding in financing this project, and the Boston Medical Library has charge of all details of organization. A final report will be made at the annual meeting. The committee is indebted to Dr. Paul J. Jakmauh, commissioner of public health, and to the United States Public Health Service for their interest and aid in helping to provide funds to finance this project.

Again this year the Society has organized clinical teaching in the diagnosis and treatment of gonorrhea and syphilis at the Boston Dispensary and the Out Patient Department of the Massachusetts General Hospital. These clinics are free and open to all legally registered physicians in Massachusetts. A final report on this phase of postgraduate instruction will be made at the annual meeting.

The third New England Postgraduate Assembly was held November 13 and 14, 1940. This was a co-operative program sponsored by the state medical societies of Maine, New Hampshire, Vermont, Massachusetts and Rhode Island. The program was excellent, and we herewith express the thanks of the societies to the following guest speakers who made the program a success:

Dr. Fred L. Adair, Chicago
 Dr. Henry W. Cave, New York City
 Dr. Russell L. Haden, Cleveland
 Dr. Sumner L. Koch, Chicago
 Dr. Robert F. Loeb, New York City
 Dr. Harrison S. Martland, Newark
 Dr. T. Grier Miller, Philadelphia
 Dr. Oliver S. Ormsby, Chicago
 Dr. P. S. Pelouze, Philadelphia
 Dr. Tracy J. Putnam, New York City
 Dr. Ralph M. Waters, Madison

The attendance at the assembly was 580 as follows:

Massachusetts	442
Maine	38
New Hampshire	34
Rhode Island	30
Vermont	27
New York	3
Connecticut	2
Montana	1
Ohio	1
Tennessee	1
Washington	1
Total	580

The attendance for the first year was 925, and for the second year, 776. The weather was doubly inclement this past year, since there was a severe rainstorm on both days. The committee believes that there should be more publicity and has appointed a committee for this purpose. On account of the lower attendance there was a deficit of \$682.18. It is expected that advance enrollment will ensure no deficit; also it has been voted to hold the assembly about mid-October, at which time better weather is anticipated.

The committee is very glad to report that the Connecticut State Medical Society, at a meeting of the House of Delegates on December 12, 1940, voted to be a co-sponsor of the next assembly. With the six New England state medical societies backing the assembly, we believe that it will be a success.

The committee recommends the following:

1. That the postgraduate extension courses, teaching clinics and postgraduate extension library be continued, as now organized, and such further co-operation with state and federal agencies be authorized as may be of educational value to the medical profession.
2. That the Society participate with the other New England state medical societies in presenting the New England Postgraduate Assembly next fall.

FRANK R. OBER, *Chairman*,
 LEROY E. PARKINS, *Secretary*.

APPENDIX NO. 12

REPORT OF THE COMMITTEE ON INDUSTRIAL HEALTH

Meetings of the Committee have been held monthly except during the three summer months. At the December meeting a member of the Council on Industrial Health of the American Medical Association was present and discussed future plans.

The committee has made a number of reports, which have been published in the *New England Journal of Medicine*, outlining the activities of the committee and presenting matters of interest to members practicing industrial medicine or considering such practice. It has reported some interesting cases of industrial origin or having an industrial interest. It has also published questions and answers to problems having to do with industrial practice.

Progress in terms of the actual results in the field is slow, but by frequent meetings and by outside contacts the committee hopes to provide an increasingly valuable service to the members of the Society.

W. IRVING CLARK, *Chairman*.

APPENDIX NO. 13

REPORT OF THE COMMITTEE ON THE ARMY MEDICAL LIBRARY AND MUSEUM

This committee has not been active in the last year except through correspondence with the senators and representatives from Massachusetts and with Colonel Harold W. Jones, librarian of the Army Medical Library.

A communication from Colonel Jones dated December 12, 1940, is as follows:

As you undoubtedly know, an appropriation of \$130,000 was made at the last session of Congress for the plans of the library and the museum. The Secretary of War has just approved the recommendation of General Magee for the appointment of an architectural firm to prepare the plans. This firm is one of the outstanding ones in the country, and there can be no doubt whatever that a building entirely in keeping with our high aims will be the eventual result. Within a few weeks I feel sure that the work of planning will be under way. The Surgeon General has indicated that preliminary plans and drawings only will be completed at this time, leaving the working drawings until a site has been definitely selected. It will probably be but a matter of a few months until it can be determined just what site will be selected, and it remains only for an appropriation to be made because there are a number of locations which would be entirely acceptable.

As you and your committee know from the investigations which you have already made, the time element is a most important one. Five years ago the library was reported to be in a serious condition so far as room for new accessions and new activities go. In those five years, through very careful planning and the utilization of every possible place including corners and corridors, and through the removal of about fifty tons of duplicate material to storage elsewhere, the librarian was able to make room for about 45,000 additional books. This space has been nearly filled now, and within one year serious embarrassment in the way of housing new accessions will be present. Within two years it is a practical certainty that a portion of the collection will have to be housed elsewhere. If action can be taken now and the new building can be started in 1941, I believe this embarrassment can be minimized, because within two years there would certainly be space in the new building, even if it were not entirely completed, to store some of our material. However, if we are to face a delay of three or four years, and the matter is postponed in the future as it has been in the past, we are indeed in a bad way. I do not suppose that I could emphasize the whole situation any better, and I feel that you will understand the anxiety that General Magee and I have over any possibility of further delay.

In view of Colonel Jones's report a second series of letters has been written to the senators and representatives from Massachusetts.

HENRY R. VILTS, MD, *Chairman*

APPENDIX NO 14

REPORT OF THE COMMITTEE TO EQUALIZE DISTRIBUTION AMONG PHYSICIANS OF MEDICAL SERVICE TO WPA EMPLOYEES

This committee has had one meeting, which was held in the WPA office in Boston on November 20, 1940. As a result of this meeting a letter was sent to each district secretary giving the names of our committee and its purpose and asking each of them to forward to us any complaints which they had or might receive from their members in regard to the distribution of medical service to WPA employees and also to inform each secretary that

any suggestions to assist this equalization would be welcomed.

Each month one of the members of our committee visits the WPA office in Boston and checks the records of payments to doctors for this service. At this time, Mr. Burns, of the WPA office, has ready for discussion or adjustment any abuses that have come to his attention.

At the end of each six months, Mr. Burns is to have a listing of all physicians doing this work according to communities and the amount of money received. This will enable us to take definite action toward equalizing the work, by dropping off from the list of available physicians the names at the top until other physicians have caught up with them as regards the amount of money collected. Mr. Burns and the committee are in agreement on the principle of genuine free choice of physicians by the injured workman.

This program sometimes meets with determined opposition. For example, one physician who had for months received far more than his share of WPA patients, and had then been cut off, appealed to his congressman for help. Many other forms of pressure are being applied to get or keep this type of practice.

This committee has no motion or recommendation to submit to the Council at this time.

GUY L. RICHARDSON, *Chairman*

APPENDIX NO 15

REPORT OF THE COMMITTEE TO CONSIDER NEW OFFICERS AND BY LAWS

Following the Council meeting of October 2, 1940, a committee was appointed by the president of the Massachusetts Medical Society to study the desirability of establishing the offices of president-elect and full time or executive secretary and to suggest the necessary changes in the by laws required to create these positions. The committee believes that these two new positions are desirable and has consequently formulated the changes in the by laws necessary for the creation of these offices.

In respect to the second part of its duties, that is, to study the propriety of altering the constitution and by laws in such a way that they would conform to those of other state medical societies, the committee reports that any attempt in the nature of redistricting involves too great a change in policy for a committee of this sort, which is probably not sufficiently representative, to act upon.

The committee has seen no need of altering the nomenclature of the governing body, the Council, or its method of election. It does recommend the creation of an Executive Committee of the Council—a smaller body, selected in such a way as fairly to represent, geographically and numerically, the fellows of the Massachusetts Medical Society.

There is also submitted a table to explain the units represented by the elected members of the Executive Committee. (The ease of geographic division is apparent if one refers to the map of the district societies in the *Directory*.)

The changes in the by laws necessitated by the creation of the offices of president-elect and executive secretary and the creation of an Executive Committee of the Council follow.

JOHN HOMANS, *Chairman*

CHAPTER III
DISTRICT SOCIETIES

Section 5. (Additional.)

The councilors of each district society shall meet as soon as possible after the annual meeting of the district society in 1941 and elect two or more of their number to serve as candidates for the Executive Committee of the Council in accordance with chapter IV, section 10; and thereafter in a similar manner they shall choose new candidates from time to time.

Section 7. (Additional.)

The secretary of each district society as soon as possible after the annual meeting of the district society in 1941 shall call together its councilors for the purpose of selecting the candidates for the Executive Committee of the Council and shall send the names of those chosen to the Secretary of the general Society. He shall see that new candidates are chosen in a similar manner to fill vacancies as they occur, in accordance with chapter IV, section 10.

CHAPTER IV
THE COUNCIL

Section 1. The Council shall consist of councilors chosen by the district societies, and the President, ex-presidents, President-Elect, Vice-President, vice-presidents *ex officio*, Secretary and Treasurer of the general Society, secretaries of the district societies, and the chairman of each standing committee.

Section 3. The Council at its annual meeting, on nomination by the Nominating Committee and/or from the floor, shall elect by ballot officers of the Society as follows: President-Elect, who shall serve as President-Elect until the annual meeting of the Society next ensuing after his election and shall become President on his installation in the course of that meeting, serving thereafter as President until the next following annual meeting and the installation of his successor; a Vice-President, Secretary and Treasurer, all of whom shall assume the duties of office at the close of the annual meeting of the Society and shall hold office until their successors have been duly elected; except only that at the annual meeting of the Society in 1941 there shall be nominated and elected a President to serve for that year. Councilors only shall be eligible to the offices above named. Upon nomination by the Nominating Committee, it shall elect by ballot a fellow to deliver an oration at the annual meeting of the Society the following year.

Upon nomination by the Nominating Committee, it shall elect by ballot members of the Executive Committee representing, respectively, the various units of district societies in accordance with section 10 of this chapter.

Section 10. The Executive Committee shall consist of the President, President-Elect, Vice-President, Treasurer and Secretary *ex officio*, the chairmen of the following standing committees, namely, Ethics and Discipline, Financial Planning and Budget, Membership, Publications and State and National Legislation, and those members elected by the Council.

The elected members, all of whom shall be councilors, shall be chosen, respectively, from geographical units of the Society so arranged that each member of the Executive Committee shall represent at least five hundred fellows of the Society as of January 1, 1941; except that if the number of fellows in any unit shall thereafter fall below five hundred, that unit shall still be entitled to its member, unless the Council orders otherwise.

These members shall be nominated and elected in the following manner:

(a) The councilors of each district society shall meet as soon as possible after its annual meeting in 1941 and in a similar manner at stated intervals thereafter, as specified below, to choose two of their number for presentation to the Nominating Committee; except that the councilors of any district society which alone represents one unit shall choose four nominees, and except that the councilors of any district society having more than five hundred fellows shall choose two additional nominees for each additional five hundred fellows or major fraction thereof.

(b) From the list of nominees representing each unit, the Nominating Committee shall choose, for election at the next annual meeting of the Council, at least twice the number of names eligible for election from that unit.

(c) From the list of councilors offered by the Nominating Committee, the Council at its annual meeting shall

Basis for Election of Members of Executive Committee of the Council.

*Based on figures of December 26, 1940.

elect by ballot, to represent each unit of district societies, one or more members to serve on the Executive Committee, according to the following plan, which may be altered by the Council at its annual meeting from time to time:

From Berkshire, Franklin, Hampden and Hampshire, designated as the Western Unit, one member.

From Worcester and Worcester North, designated as the Worcester Unit, one member.

From Middlesex North, Middlesex South and Middlesex East, designated as the Middlesex Unit, two members.

From Essex North and Essex South, designated as the Essex Unit, one member

From Suffolk, designated as the Suffolk Unit, one member

From Norfolk and Norfolk South, designated as the Norfolk Unit, two members

From Plymouth, Bristol North, Bristol South and Barnstable, designated as the Cape Unit, one member

(d) The members of the Executive Committee shall serve for three years and shall not be eligible for re election before the expiration of three years following the conclusion of their terms of office, except that in 1941 three members shall be selected by lot to serve one year, three members shall be selected by lot to serve two years and three members shall be selected by lot to serve three years. Thereafter three members shall be elected every year to succeed in office those whose terms are about to expire and shall be nominated by the councilors of the various district societies concerned, as already described in subsections a, b and c of this section, unless the Council otherwise directs.

The Executive Committee shall meet at the call of the President at least once in each interval between Council meetings and may meet oftener at the pleasure of the President. It shall assist the President in preparing for the consideration of the Council matters calling for action by the Council at its next meeting. It shall authorize action when circumstances require it, subject to the approval of the Council. It shall perform such other duties as the Council may require.

The consent of the Executive Committee shall be required to confirm the appointment, upon nomination by the President, of the Executive Secretary of the Society.

Upon request, members of the Executive Committee shall be paid the amount of their traveling expenses from the funds of the Society.

CHAPTER V

CENSORS AND SUPERVISORS

Section 1 The supervisors, representing the censors of the several district societies, shall constitute a board, which shall meet annually on the day appointed for the annual meeting of the Council. The board shall elect a chairman, who shall have power to call special meetings. Five supervisors shall constitute a quorum. The secretary or executive secretary of the general Society shall act as secretary of the board. He shall keep a permanent record of the proceedings of the board, and shall provide, at the expense of the Society, papers and forms necessary for conducting examinations of applicants for fellowship. The board at its annual meeting shall adopt a uniform plan for the examination of applicants. The supervisors shall be paid the amount of their traveling expenses from the funds of the Society.

CHAPTER VI

OFFICERS

Section 1 (Additional)

He shall call at least one meeting of the Executive Committee of the Council between Council meetings and may call more meetings if he so desires.

Section 2 In the absence of the President, the Vice President shall perform all the duties of the President, and in the absence of both, the senior Vice President *ex officio* in point of membership shall perform the duties of the President.

Section 3 The President Elect shall assist the President in the performance of his duties in such a manner as the

President may direct and in so doing shall be considered to represent the President.

In the absence of the President Elect, the Council, at its next annual meeting, shall, upon nomination by the Nominating Committee and/or from the floor, elect a President.

Section 4 The Secretary may assign to the Executive Secretary any or all of the duties now to be enumerated, except as specified below.

The Secretary shall attend all meetings of the Society and of the Council, and shall record their respective proceedings in separate record books, and this duty he may not assign.

He shall cause to be engrossed and shall sign the diplomas of new fellows if satisfied that they have met the requirements of sections 1 and 2 of chapter 1, and shall issue all diplomas and certificates of fellowship. He shall notify individual fellows, in appropriate instances, of votes by the Council granting permission, as the case may be, to retire, to resign, to change district membership, to have dues remitted, or of votes depriving them of the privileges of fellowship, and these duties he may not assign.

He shall act *ex officio* as secretary of all boards of trial, and this duty he may not assign.

He shall have custody of the seal of the Society and of all books, papers, manuscripts, prints and paintings belonging to the Society, except such as are in charge of the Treasurer, and this duty he may not assign.

He shall act *ex officio* as secretary of the Board of Supervisors and of the Committee on Publications and the Committee on Ethics and Discipline, and shall keep the records of each in a separate volume. He shall have custody of all records as thus kept.

He shall issue notices of the meetings of the Council. One month before the annual meeting of the Society he shall issue to every fellow a program which shall contain: (a) notification of the time and place of the annual meeting, (b) notification of the stated meetings of the Council for the year, and the meetings of the boards of censors, (c) information concerning the payment of assessments, and the distribution of publications.

He shall record the proceedings of the Council and of the Society. He shall keep a complete list of the fellows of the Society, with their addresses so far as known. He shall transfer fellows from one district to another under the terms of chapter III, section 2, and shall report to the Society at its annual meeting the changes in membership of the Society during the year.

He shall conduct the official correspondence of the Society, and shall notify officers, delegates, and members of the committees of the general Society of their appointments and of their duties.

Under the direction of the Committee on Publications he shall issue at such intervals as may be determined by the Council a directory of officers and fellows of the Society, which shall be furnished upon request to fellows who are not in arrears.

He shall perform such other duties as the Society or the Council may require.

Section 5 The Executive Secretary shall be chosen by the Executive Committee of the Council upon nomination by the President. He shall hold office for one year or until his successor has been duly elected.

He shall perform such duties as are assigned to him in section 4 of this chapter and by the Executive Committee. In general, he shall assist the officers of the So-

ciety and such standing and other committees as may request his services, and his preoccupation shall be the service of the Society.

He shall attend all meetings of the Council and, on request, attend the meetings of the Executive Committee of the Council, but shall not vote in either.

The Executive Secretary need not be a fellow of the Society and nothing in this section shall forbid the choice of a woman for the office.

APPENDIX NO. 17

REPORTS OF COMMITTEES TO CONSIDER PETITIONS FOR RESTORATION TO THE PRIVILEGES OF FELLOWSHIP

Restoration to fellowship, with the usual provision regarding payment of dues, was recommended for the following ten former members:

Edward T. Abrahams, Pittsfield (Committee: Charles T. Leslie, Modestino Criscitiello, Jr., and I. S. F. Dodd).
 Elmer J. Beaulieu, Whitman (Committee: Walter H. Pulsifer, Joseph H. Dunn and Alfred C. Smith).
 Joseph J. Carella, Quincy (Committee: Charles S. Adams, T. Vincent Corsini and Alfred V. Mahoney).
 L. W. Darrah, Northampton (Committee: Justin E. Hayes, Michael E. Cooney and Joseph R. Hobbs).
 Harry J. Hagerty, Worcester (Committee: John H. Hartnett, Peter A. Colberg and Julius J. Tegelberg).
 Morris J. Ritchie, Westfield (Committee: Archibald J. Douglas, Edward S. Smith and Robert M. Marr).
 Joseph Rosenthal, Roxbury (Committee: Sidney H. Weiner, Hyman Morrison and Joseph Laserson).
 Kent T. Royal, North Brookfield (Committee: James C. Austin, Milman Pease and Thomas J. O'Boyle).
 Robert V. Schultz, New York City (Committee: Joseph D. Ferrone, Oliver G. Tinkham and M. Fletcher Eades).
 Honoria K. Shine, Holyoke (Committee: Edward P. Bagg, George D. Henderson and Patrick E. Gear).

APPENDIX NO. 18

COMMITTEES APPOINTED TO CONSIDER APPLICATIONS FOR RESTORATION TO FELLOWSHIP

The following committees were appointed to consider the petitions for restoration to fellowship of the following four former members:

For Anthony P. Carogana, Chelsea:
 William J. Brickley, Judson A. Smith and Walter E. Garrey.
 For William R. Hill, Brookline:
 Charles J. Kickham, James A. Hennessey and Robert J. Donovan.
 For Charles H. Hogan, Salem:
 Charles L. Curtis, Thomas F. Henry and Stuart N. Gardner.
 For Arthur J. Taveira, New Bedford:
 Frank M. Howes, Edwin D. Gardner and Curtis C. Tripp.

APPENDIX NO. 19

LETTER FROM DR. HERBERT MARGOLIS

Because of certain practices now prevalent in Massachusetts, children who go to private dentists' offices for treatment, and whose parents finance such work, are penalized in regard to school attendance records. It is a common practice to send from six or eight to a busload of children from a school to a free or publicly financed dental clinic, allowing these children to be away from school an entire morning, although each one is operated upon for only twenty minutes to three quarters of an hour at the most. These children are considered to be in attendance at school during this time and are not marked absent. The school curriculum is so arranged that they lose nothing in lessons through this long absence.

In contrast to this, if a child presents a dental appointment card and asks to be excused from school to keep

an appointment in a nearby dentist's office this child is marked absent, and many times school superintendents and teachers are very much annoyed by this practice and make it unpleasant for the child.

The Oral Hygiene Council of Massachusetts believes that something should be done about this. We have considered legislation, but this seems inadvisable. It has been suggested that it would be better to work amicably through school departments gradually to change this attitude in local schools. We should like to start in Boston and be able to use Boston as an example to other localities. We understand that there is a regulation of the Boston School Committee which permits children to attend clinics and hospitals without being considered absentees. The Oral Hygiene Council would like to suggest to them that they

change this rule so that it would excuse a child for medical and dental service which, of course, covers private medical and dental service as well as clinic and hospital service.

Since this rule mentions medical as well as dental service, would the Massachusetts Medical Society go on record as joining with the Oral Hygiene Council in requesting the Boston School Committee to make this change in their regulations? Will you kindly present this to the councilors at their next meeting, and notify us of their decision in the matter?

HERBERT MARGOLIS

MEDICAL PROGRESS

PSYCHIATRY

Pharmacologic Shock

VERNON P. WILLIAMS, MD*

BOSTON

ALTHOUGH insulin and Metrazol shock therapy in the psychoses continues, results have been reported far less prolifically than in previous years. No doubt this is in part owing to the fact that the percentages of remissions, recoveries and improvements have not been large enough to support the original enthusiasm for such therapy, and consequently such treatment is not being conducted on so large a scale as in the past. Furthermore, it is still true that more time must pass before the remissions obtained can be adequately balanced prognostically against the percentages of remissions in cases not treated by shock therapy.

Read,¹ of the Elgin (Illinois) State Hospital, reporting on the status of 386 schizophrenic patients at least twelve months after the completion of Metrazol or insulin treatment, states that the percentage of mental improvements was less than that claimed for spontaneous remissions. In writing on insulin treatment of 76 cases of schizophrenia in China,—most of the patients being Chinese,—Halpern² says, "A higher percentage of patients in China, compared with those in western countries, proved to be unfit for insulin shock treatment. Observations point more to climatic than to racial differences." Complications making the treatment impossible occurred during an especially hot season. Bateman and Michael,³ reporting on shock treatment of schizophrenia in Ohio state hospitals since 1937, consider that the results

justify the continued use of insulin shock in patients whose illness has been less than two years

LOBOTOMY

However divided opinion may be about the value of the pharmacologic treatment of the major psychoses, the attack on them with specific, tangible, physical agents continues unabated. The surgical procedure of lobotomy, the undercutting of certain areas in the frontal lobes of the brain, has been found to give relief in cases of agitated depression. This operation, originally performed by Moniz⁴ in Portugal, has been done in the United States, particularly by Freeman and Watts⁵ and Lyster.⁶ The criticism of this drastic treatment is that patients who undergo it, though freed from their almost unbearable tension and depression, are apt to be left with a marked inertia and striking deficit in constructively directed energy and interest. It is generally agreed that the operation should be reserved for patients well past middle age whose chance of spontaneous recovery seems negligible. Also, as Cobb⁷ points out it should be remembered that the operation may leave scar and necrotic tissue that can later cause epilepsy.

ELECTRIC SHOCK

The desire to do something for patients suffering with psychoses is, of course, commendable, but the recently initiated electric shock therapy

*Assistant in psychiatry, Massachusetts General Hospital.

does not seem to stand on a soundly worked-out scientific basis. Comparatively little has been published so far about this treatment, but its modern application began with the work of Cerletti and Bini⁸ a few years ago. It has recently been instituted in numerous hospitals in this country, but apparently patients have been subjected to electric currents of various voltages without the estimation first, by animal experimentation, of the extent of possible injury or damage to the nervous system. Berkwitz,⁹ reporting the results obtained in treating over 1000 schizophrenic patients with the faradic current, says, "Electric convulsive therapy is now being introduced as a substitute for Metrazol convulsive shock therapy, but whether it is safer has not yet been established." He adds that the beneficial results parallel those noted with other forms of shock therapy.

Sogliani¹⁰ reports that he has found electric shock therapy effective in long-standing cases of depressive psychosis. But it must be said of this treatment, as of pharmacologic shock, that it has not been used long enough to determine its ultimate value.

ANOXIA FOR THE PSYCHOSES

Physiologic investigations with insulin and Metrazol therapy suggest that the drugs may produce their ameliorative effects through the mechanism of cerebral anemia. Consequently, anoxia, produced by the inhalation of nitrogen or nitrous oxide, has been introduced as another method in treatment of the psychoses. To date this work has not been extensively reported. Fogel and Gray¹¹ have used nitrous oxide in 24 cases of schizophrenia. In 10 of these patients, whose illness was of one year or less in duration, remissions or improvement occurred in 70 per cent. Improvement was less satisfactory in patients whose illness had existed for two to five years, and 4 patients whose psychoses had persisted for longer than five years showed no improvement. These investigators point out the well-known fact that there is danger of permanent injury to the cortex from nitrous oxide inhalation.

Green and Adriani¹² report practically no improvement in a series of 24 patients who were treated with inhalations of nitrogen. Nineteen of these cases were diagnosed as schizophrenia, 4 as manic-depressive psychosis, and 1 as anxiety neurosis. In general the duration of the psychosis should not be a factor in the result.

PSYCHOLOGIC INFLUENCES

The fascinating problem of how much human behavior is dependent on so-called "psychologic"

forces acting from without on the organism or personality is always present for the psychiatrist. When a person reacts this way or that, under the influence of another person or in a situation of emotional importance to him, it can always be safely argued that he would have reacted differently if he had been constituted differently. It cannot be claimed, however, as conceivable that any human being ever existed with such an impregnable constitution that he would be unresponsive to all environmental, emotional or psychologic influences. Such a human being would have to develop without a brain-stem, and to date biologic forces have not produced such a human animal. Even among doctors, who should have a proclivity for scientific thinking, there is a tendency, on the one hand, to see all disease and behavior as being "organically" determined, and on the other, to think of them as being primarily caused or induced by intangible psychologic and emotional drives, conflicts or frustrations.

The truth, so far as is known, is that mind and matter are one. A certain reaction, say of fear, may be initiated within the body because of retinal stimulation by light waves from an external object or because of sound waves stimulating the auditory nerves. And in some cases physiologic malfunctioning within one or another or various systems of the body may produce abnormal physical or mental reactions.

It is with this conception in mind that the schizophrenic reaction might be considered. It is possible and probable that certain persons, because of hereditary or endogenous defect, will develop a schizophrenic psychosis, no matter what environmental influences play upon them. Others may never develop schizophrenia, either because the accidents of their environments have not been of a kind to start in them such a process or because the makings, whatever they are, of the psychosis do not reside within them.

Postle¹³ reports an interesting example of *folie à deux*, apparently illustrating the tremendous importance of one personality on another in the development of a chronic schizophrenic psychosis. When the dominant person died, the psychotic reaction, of twenty-five years' duration, cleared in the passive partner, and she made a satisfactory social recovery, which had been maintained for over two years at the time of Postle's report. It cannot, of course, be claimed that the removal by death of one psychotic person was the cause of the remission in the other, but the circumstances as reported are strongly suggestive of this. If this is so, it should not be concluded without caution

that irreversible changes of a physical nature occur in the brain of a schizophrenic patient.

An interesting example of the influence of ideas, carrying emotional significance for the patient, on functioning of body organs, is given by Faulkner.^{14,15} He reports on esophageal spasm in 13 patients. With the esophagoscope in place, he noted marked spasm or relaxation of the esophagus when he made remarks, respectively, that he knew from the patients' histories would be likely to produce either unpleasant or pleasant emotional response. Faulkner¹⁴ states also that he has seen 3 cases in which the bronchus widened or tightened in response to emotionally pleasing or disquieting suggestions.

PSYCHIATRIC EDUCATION

The importance of sound psychiatric education in medical schools and during internship training is still not adequately appreciated. The medical student is inclined to look on the required courses in psychiatry as being somewhat unworthy of serious attention, particularly since he envisions having little to do with insane people in later years. Psychiatry is likely to seem to the student a matter of keeping the insane locked up somewhere, and psychiatrists are too often thought of as being a little queer themselves, as thinking only in terms of sex and Oedipus complexes, and as being removed from the practical world of surgery and medicine.

This attitude is unfortunate, since, as every practicing doctor knows, over a third of the patients seen in hospitals or private practice require or should have psychiatric attention. The relation between personality maladjustment and the complaints for which the patient consults his doctor becomes more and more obvious, and if the doctor is not interested in or does not know how to deal with emotional problems, he will not give his patients proper service.

An admirable curriculum for psychiatric teaching and therapy has been established in the University of Colorado School of Medicine and Hospitals, under the direction of Billings and Ebaugh. As reported by Billings,¹⁶ the services of the psychi-

atric department are nicely interwoven with those of the other hospital clinics and departments.

ATTACK ON PROBLEMS OF ALCOHOL

In January, 1938, the Research Council on Problems of Alcohol was incorporated as an associated society of the American Association for the Advancement of Science. Believing that "the alcohol problem has become one of the major perplexities of our civilization," the council is to study the problem scientifically and to deal with it in the same general fashion as syphilis, tuberculosis and cancer have been attacked as major health problems.

Until the end of 1941 the council will concentrate its attention on alcoholism and the alcoholic psychoses. In connection with the plans of the council, the first number of the *Quarterly Journal of Studies on Alcohol* was issued in June, 1940. Therein are many articles of value to those interested in the problems of alcohol.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27091

PRESENTATION OF CASE

A fifty-two-year-old woman entered the hospital complaining of crampy abdominal pain and vomiting of three weeks' duration.

The patient was seen for the first time approximately nine months before admission, when she complained of frequency, urgency and burning on urination, with a nocturia of four to five times. Further, she suffered from cramplike suprapubic pain during and immediately after urination. These symptoms had appeared three months previously and gradually increased in severity. She was admitted to this hospital, where examination of the urine showed a + test for albumin, with 20 red and 20 white cells per high-power field, and a culture yielded an abundant growth of colon bacilli. Cystoscopic examination showed a small, delicate, papillary growth with exceedingly fine fronds situated near the left ureteral orifice. The bladder was moderately inflamed, with a little yellow exudate adherent to the wall high up on the base. The growth was destroyed completely with the coagulating current and Bugbee electrode. Postoperatively the infection rapidly disappeared with sulfanilamide therapy, and the patient was discharged one week after admission.

Five weeks later the urine became cloudy and full of pus and blood. Cystoscopic examination showed the area previously occupied by the tumor to be covered with a little superficial slough, but there was no visible tumor. Above this, however, in the dome of the bladder was a rough irregular area, 1.5 cm. in diameter, which was ulcerated and had the appearance of cancerous infiltration. A biopsy from this point was reported as carcinoma (unsatisfactory for grading). Operation was advised but refused. During the next month the patient received 8400 r of supervoltage radiation, and two weeks later the urine was clear, the patient symptom-free and cystoscopic examination showed marked regression of the tumor. An additional 3600 r of external radiation was administered over the next ten days, and one week later no tumor could be seen in the bladder, the area being occupied by a flat, yellowish, irregular area that grossly resembled a scar from radiation reac-

tion. At no time was there palpable thickening of the bladder base on rectal or vaginal examination. Cystoscopic examinations five weeks and three months later showed pallor of the bladder mucosa and reduction in capacity, but no sign of tumor. Three weeks before entry the patient developed a crampy, upper abdominal pain accompanied by frequent vomiting. These symptoms grew steadily worse, and during the few days preceding admission she was unable to retain any food and constipation developed.

The patient had had scarlet fever at four years of age, an appendectomy and uterine suspension twenty-three years before admission, a right simple mastectomy for a benign tumor three years later, and a right mastoidectomy eighteen years before admission. One sister had died of carcinoma of the breast at fifty-two. The patient's husband had died of tuberculosis twenty-three years previously, and two children had died of tuberculosis of the kidneys at one and two years of age respectively.

On examination the patient was acutely ill and dehydrated. Examination of the heart and lungs was negative; the blood pressure was 120 systolic, 78 diastolic. The abdomen was distended and slightly but diffusely tender, with active peristalsis.

The temperature was 97°F., the pulse 130, and the respirations 25.

Examination of the urine showed a + test for albumin, an olive sugar reaction and a +++ test for acetone. The sediment contained an occasional granular and hyaline cast, with 3 red blood cells and 5 white blood cells per high-power field. Examination of the blood showed a red-cell count of 4,650,000 with a hemoglobin of 16.1 gm. (photoelectric-cell technic), and a white-cell count of 4300 with 70 per cent polymorphonuclears.

Plain x-ray films of the abdomen showed one gas-filled loop of intestine in the left upper quadrant, which had the appearance of jejunum. This loop was not dilated.

The day after admission a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. ERNEST M. DALAND: We are not told whether there was a biopsy at the time of cystoscopy. The description of the growth is interesting. It was a small "delicate" papillary growth with exceedingly fine fronds. I think they mean to tell us that this was a papillary growth that was not suggestive enough of cancer to warrant biopsy. The story is characteristic of papillary growths in the bladder. One area was destroyed, and a short time later another area was found, which proved

to be cancer. The first lesion was near the ureteral orifice, and the second was in the dome.

Two weeks after irradiation was started there was marked regression of the tumor. That is an exceedingly good sign and may be interpreted as evidence of a sensitive tumor, which probably will be taken care of by x-ray irradiation before the cycle is finished. At the end of about three weeks the tumor had entirely disappeared. The patient had a good deal of x-ray therapy, — 8400 plus 3600 r, — and we have reason to suspect that there may have been a great deal of reaction around the site of that tumor.

Cystoscopic examinations five weeks and three months later showed pallor of the bladder mucosa and reduction in capacity, but no sign of tumor. One recalls that the tumor had been 15 cm in diameter. One would hardly expect that destruction of that tumor alone would be enough to cause reduction in capacity of the bladder unless there were a good deal of inflammatory reaction around it.

"... during the few days preceding admission she was unable to retain food and constipation developed." I wonder what they meant by constipation; it usually means either difficulty in or lack of bowel movements. She had been vomiting everything eaten for the last few days and had had no food, and I therefore think that bowel movements could hardly be expected. They do not tell us whether the peristalsis was high pitched or not.

We have, then, a patient with a long-standing story of obvious intestinal obstruction, and three weeks of vomiting and abdominal pain. The pain was in the upper abdomen, and that usually points to small bowel obstruction. She was very much dehydrated, as evidenced by the high red-cell count and the high hemoglobin. The white-cell count of 4300 shows that there was probably no interference with the blood supply of the bowel.

May we see the x-ray films?

DR GEORGE W. HOLMES. These films, which I presume are the ones Dr. Daland is interested in at the moment, show the loops of gas filled small bowel. I should not think that they were particularly dilated, although they are perhaps a little large. From the story we have just heard, one might expect much more dilatation than these films show. There is very little gas in the large bowel, which is of some importance, pointing toward obstruction in the small bowel. The kidney outlines are distinctly seen on both sides and are normal in shape, so that the patient did not have hydronephrosis, and there is no evidence of metastasis to the bones of the spine.

DR. DALAND. We have, then, an intestinal obstruction, probably of the small bowel. We must consider the possibility of a cancerous implant, metastatic in the small bowel, with obstruction. We must consider an implant in the terminal ileum, with an intussusception, but nothing is said about any palpable mass in the region of the ileocecal valve. We might have obstruction by a gallstone, but I think that is unlikely. We might have an independent new growth of the small bowel, but carcinomas of the small bowel are quite rare. Lymphomas are a little commoner than carcinomas, but here we have a patient who has had a known carcinoma of the bladder and a great deal of irradiation, with undoubtedly a good deal of reaction around it. We cannot expect x-rays focused on the wall of the bladder to destroy a lesion in this short time without getting a certain amount of reaction throughout the wall of the bladder and in the adjacent structures. We do have to consider very strongly the possibility that a loop of bowel got stuck to the bladder or the peritoneum over the bladder, producing a partial obstruction. With a white-cell count of 4300 and a normal temperature, there was probably no gangrenous loop or much free fluid. My diagnosis, then, is small bowel obstruction, probably in about the mid ileum, caused by adherence of the bowel to the peritoneum over the bladder at the site of the x-ray treatment.

DR. FLETCHER COLBY. I thought very much as Dr. Daland does: that this woman apparently had obstruction of some portion of the bowel as a result of the large amount of irradiation she had had. This was an acute episode that came on several months after irradiation.

The only other thing that I have to add is that the patient did have a malignant tumor of the bladder, proved by biopsy. She has been cystoscoped at regular intervals since irradiation and has had no recurrence, although her bladder is of somewhat smaller capacity than normal.

DR. CLAUDE WELCH. The three diagnoses that Dr. Colby and I considered in this case were radiation necrosis of the lower small bowel with obstruction, some obstruction from bands around the site of the previous abdominal operation, and extension from carcinoma of the bladder involving the small bowel. Much to my surprise, there was a carcinoma of the transverse colon about the size of my thumbnail and bound down to the left side of the bladder at exactly the spot where she had been receiving all the irradiation. That had been present with absolutely no gas visible by x-ray study of the ascending colon. The

patient's progress was satisfactory following the resection.

PREOPERATIVE DIAGNOSIS

Intestinal obstruction.

DR. DALAND'S DIAGNOSIS

Intestinal obstruction, due to loop of ileum adherent to radiated area in bladder.

ANATOMIC DIAGNOSIS

Adenocarcinoma of the transverse colon.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The diagnosis of post-radiation reaction was certainly a very reasonable one to make in this case. We have seen several cases in which an adherent loop of bowel in the field of radiation has developed a severe reaction, in the course of which the bowel wall has become markedly thickened by fibrous tissue. These cases present obstructive symptoms in spite of the fact that the lumen of the bowel may not show much stenosis. The carcinoma found by Dr. Welch was a typical primary adenocarcinoma of the cecum. Here is a case in which we have three entirely different neoplasias: a tumor of the breast ten years before admission, cancer of the bladder and then a cancer of the large bowel. It is rather interesting that this tumor, which was adherent to the bladder, must have been in the field of radiation. The bladder tumor was apparently cured by the supervoltage radiation, but the intestinal tumor, which must have received identical dosage so far as we could make out, was not touched by it. This is, of course, in line with our clinical experience that radiation therapy of intestinal carcinomas is a waste of time. It is seldom that one has so well-controlled an observation as this.

DR. HOLMES: Did the normal bowel in the field of radiation show any reaction?

DR. WELCH: There was marked thickening—up to 2.5 cm.—of the transverse mesocolon, which made the operative procedure a little different from that ordinarily employed, because no anastomosis could be thought of in that tissue. The same reaction was still present when the patient was operated on about two months later for closure of the fecal fistula.

DR. MALLORY: You found nothing to indicate that there was ever any small-bowel obstruction?

DR. WELCH: No; it was thoroughly examined and perfectly free all the way through.

CASE 27092

PRESENTATION OF CASE

A fifty-two-year-old housewife entered the hospital complaining of vomiting of three weeks' duration.

The patient was treated in this hospital for the first time eight years before admission, when a complete hysterectomy, bilateral salpingo-oophorectomy and appendectomy were performed. The pathological report was chronic endocervicitis and endometriosis of the appendix. X-ray findings in the chest at the time were those of healed bilateral apical tuberculosis. She was seen again three years before admission, and complained of nervousness, fatigue, weakness, indigestion, nocturia and dysuria, but examination was negative. One year before admission the patient came to the Out Patient Department complaining of constipation, gas in the stomach, insomnia and nervousness and stated that she had had two small hemoptyses two months previously. A gastrointestinal series showed a small hiatus hernia of the esophagus. The stomach filled well, with normal relief; the pylorus opened readily, filling a normal cap and duodenum. The head of the motor meal lay in the transverse colon, the tail in the terminal ileum. A film of the chest showed slight mottling in the right apex. The heart shadow was in the upper limits of normal, the aorta was tortuous but normal, although there was questionable widening in the oblique view. Pulsations were strong, even out into the lung roots, and a Corrigan type of pulsation was suggested. Ten months before admission, after taking a "nerve tonic," the patient coughed up "a few drops of blood." She went to another hospital, where x-rays were taken and admission was advised but declined. X-ray studies were repeated five months before admission, and she was told that she had tuberculosis, with a positive sputum. One month before admission, the patient entered the above hospital, where x-ray examination showed "no germ and no effect on the lungs." On the fifth hospital day vomiting developed and became a persistent symptom. In addition she became "deep yellow in color for two to three weeks." Vomiting usually occurred in small amounts every two or three hours, but occasionally it ceased for as long as three days, after which "a bucketful" was expelled. The patient left the hospital within three weeks and went home to bed, where her physician administered a series of about thirty "liver injections." She entered this hospital a few days after the last injection.

On examination the patient was in shock and

vomiting foul, blackish fluid almost constantly. The pupils were constricted, the extremities cold and clammy; and the skin had a slightly icteric hue, but no other abnormal pigmentation. The heart sounds were somewhat distant, but otherwise normal; the blood pressure was 120 systolic, 80 diastolic, but could not be obtained shortly after admission; the pulse was just perceptible. Examination of the lungs was negative. The abdomen was held in protective spasm, but no masses could be felt other than the liver, which was palpable three fingerbreadths below the costal margin. Pelvic examination was negative. The reflexes were sluggish, but equal; Trousseau's sign was positive.

The temperature was 101.8°F, the pulse 120, and the respirations 20.

Examination of the urine showed a +++ test for albumin, with occasional hyaline and granular casts and 5 red blood cells and 20 white blood cells per high power field in the sediment. Examination of the blood showed a red cell count of 4,240,000 with a hemoglobin of 8.3 gm (photoelectric-cell technic), and a white-cell count of 21,600 with 85 per cent polymorphonuclears. The red cells showed achromia, with variation in size and shape; 2 per cent were nucleated. The nonprotein nitrogen of the blood serum was 60 mg per 100 cc, the chloride 101.5 milliequiv per liter, and the carbon dioxide combining power 26.3 milliequiv. A blood Hinton test was negative. The stools were normal, and the vomitus contained no free hydrochloric acid and was guaiac negative.

With a gastrointestinal series the stomach contained a 90 per cent residue of barium, together with a large amount of secretion six hours after a motor meal. The stomach was grossly dilated, and there was dilatation of the pyloric valve and duodenum around to the third portion, where there was a marked constriction. It was not possible to examine this area in a satisfactory manner because of the dilute barium. In the films, however, there was a suggestion of a polypoid defect just beyond the area of narrowing.

The patient was given two 500-cc blood transfusions and intravenous glucose and physiologic saline solutions, but continued to vomit large quantities. Three days after admission she became drowsy. The urinary output never rose above 100 cc, and averaged 250 cc; the nonprotein nitrogen rose to 90 mg per 100 cc, and the vomitus became guaiac positive. On the fourth hospital day a jejunostomy was performed under local anesthesia, but because of inadequate exposure no evidence of tumor or cause for duodenal

obstruction could be found; the chloride was 110 milliequiv, and the carbon dioxide combining power 36.8 milliequiv per liter. The next day, drowsiness increased, and at times the patient became irrational; the temperature rose to 104°F. The reflexes were very active, and involuntary twitchings of the jaw and extremities occurred. The nonprotein nitrogen was 85 mg per 100 cc, the protein 4.9 gm, the chloride 99.5 milliequiv per liter, and the carbon dioxide combining power 31.5 milliequiv. One week after admission the temperature again rose to 104°F, and the pulse and respirations became elevated. The left chest was dull to percussion below the sixth dorsal vertebra posteriorly, with scattered areas of bronchial breathing and occasional dry crackling rales throughout both lungs. The abdomen was distended, peristalsis was absent, and there was tenderness with marked spasm in the left flank. Despite oxygen therapy and another blood transfusion, the patient died the next day.

DIFFERENTIAL DIAGNOSIS

DR E PARKER HAYDEN This history suggests several possible causes of intestinal obstruction. The patient had had a previous abdominal operation. She had tuberculosis. She had had endometriosis. Any one of these might be the cause of her later obstruction.

We do not know whether the protective spasm was voluntary, or whether it was true spasm, suggesting peritonitis. If she had an advanced peritonitis with much spasm, it would probably be difficult to feel the liver.

The description of a polypoid defect in the x-ray film, of course, suggests a tumor, but this appearance might be due to a gallstone impacted in the duodenum. Apparently there were no positive operative findings, the patient's condition probably rendering extensive exploration unwise, and the surgeon restricted himself to a jejunostomy under local anesthesia to relieve what was evidently a very high obstruction in the third portion of the duodenum near the tail of the pancreas, possibly in relation to the stomach or transverse colon.

The first diagnosis that occurred to me was that of carcinoma of the duodenum. Cancer of the duodenum is very uncommon, however, and when present is apt to be in the region of the papilla, whereas the obstruction here was obviously farther down, near the end of the duodenum. I shall therefore discard this diagnosis. Another possibility is secondary involvement of the duodenum by a cancer arising elsewhere. Cancer of the pancreas, for example, will sometimes invade the duodenal wall and produce obstruction. The evidence

is insufficient to rule this possibility either in or out.

The jaundice several weeks before entry, if it was true jaundice, could, of course, have been due to obstruction of the common duct prior to rupture of a gallstone into the duodenum. It could have been caused by metastatic disease of the liver, or by carcinoma of the pancreas, but since the jaundice was very slight on admission, whereas previously it had been pronounced, a stone would best explain that sequence of events.

There seems no doubt that the patient had tuberculosis, and therefore the possibility of a tuberculous lesion of the bowel with obstruction must be considered. I have never seen such a lesion in the duodenum or upper jejunum, but I should think it could exist. It seems that perforation had occurred, presumably at the obstructing point, perhaps to produce an abscess either in the lesser peritoneal cavity or in the left upper quadrant, probably with subsequent generalized spread of the peritonitis.

The whole picture may have been due to tuberculosis, with development, toward the end, of a tuberculous meningitis accounting for the various nervous symptoms, with terminal pneumonia and death. I think it is anybody's guess whether this patient's obstruction was due to a tuberculous stricture or to carcinoma of the duodenum. In all probability, it was not a gallstone. In view of the known presence of tuberculosis, I am making a first diagnosis of a tuberculous stricture involving the small bowel, although the observation of a polypoid defect, unless due to a fecalith, does not fit this diagnosis.

DR. AUBREY O. HAMPTON: I think we can be perfectly certain that the obstruction was in the duodenum, in the third portion behind the stomach. Even though the barium is dilute, one can make out in the duodenum a round defect that looks like a round polypoid tumor, not like an inflammatory lesion. I think that we must rule

out gallstone. There is no evidence that a stone had perforated into the duodenum from the gall bladder.

CLINICAL DIAGNOSES

Duodenal obstruction.

Peritonitis, acute?

Uremia.

Bronchopneumonia.

DR. HAYDEN'S DIAGNOSIS

Tuberculous stricture of the duodenum, with perforation and peritonitis.

ANATOMIC DIAGNOSES

Carcinoma of the duodenum.

Peritonitis, generalized.

Bronchopneumonia.

Pulmonary tuberculosis, healed apical, bilateral.

Operative wound: jejunostomy.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The post-mortem examination in this case showed a primary carcinoma of the terminal portion of the duodenum, just edging over into the first part of the jejunum and lying directly behind the ligament of Treitz. It was a polypoid growth, with little invasion of the wall, and was evidently of a low grade of malignancy. Its location would have made resection difficult, but if one could have avoided the blood vessels in the root of the mesentery, it might have been possible at an earlier stage before the obstructive symptoms became so severe. The patient came in, obviously, almost moribund. Following the jejunostomy, general peritonitis developed. There were 2000 cc. of foul purulent fluid in the peritoneal cavity. The only other findings of significance were a rather extensive but inactive tuberculosis of the lungs and a terminal bronchopneumonia.

GRADUATE MEDICAL EDUCATION AND DEFENSE

THIS nation, as well as all others, stands at the crossroads. Each is in dire peril. Under such circumstances, the general health of the nation is of the utmost importance. Those who protect this national health—the physicians and surgeons of the country—must undergo a long and arduous training before they are able adequately to undertake the task before them. When crises are at hand, there is a tendency on the part of many to rush their fences and to seek means whereby their goal may be more quickly reached. Yet the process of medical education cannot and must not be too sharply curtailed. The report of the

Commission on Graduate Medical Education* outlines in a clear and concise manner the desirable and necessary features of each of the graduate periods—the internship, the residency and postgraduate education. All those even remotely interested in the subject—and every doctor should be—ought to read this report. In essence its recommendations are covered in the following paragraphs.

The internship, which rounds out the medical-school course and gives to it practical application, should train men for general practice,—even though a man intends to enter a specialty,—should be at least eighteen months long and should be so designed that the intern will have considerable responsibility under adequate supervision. The short, rapidly rotating type of service is considered unsound.

The residency, which prepares a man for the practice of a specialty,—and which perforce is preceded by an adequate internship,—should, according to the Advisory Board of Medical Specialties, be of at least three years' duration and should include some advanced training in the basic medical sciences. The committee believes that unless these requirements are met physicians may "find it difficult to complete their training and yet will be tempted to practice their chosen specialty in spite of their incomplete preparation."

True postgraduate education, which may come at any subsequent period of a doctor's career, should aim to keep him abreast of current knowledge and should teach what of the old should be discarded and what of the new is worth embracing. It should not—in the committee's opinion—be designed to qualify a physician for entering a specialized field of practice. It should be remembered, however, that postgraduate education is divided into two independent categories, which should clearly be differentiated, namely, that designed for the instruction of general practitioners and that designed for those already qualified as specialists. The committee further very properly recommends that such instruction be given only

**Graduate Medical Education*. Report of the Commission on Graduate Medical Education. 304 pp. Chicago: University of Chicago Press, 1940.

by those duly qualified and that it should be coordinated by "existing agencies in each state that are concerned with the health and medical care of the population."

With the nation's health becoming more and more important and with the increasing exigencies of military service,—both line and medical,—the recommendations of this committee should be studied carefully by all those concerned with the training of physicians and by those who may have to do with the transfer of physicians from civil to military life.

NURSING FACILITIES IN AND ABOUT BOSTON

In sickness, there can be no doubt that the nurse plays and always will play an extremely important and often an indispensable role. On this point all are agreed. Physicians, by and large, are familiar with the public and private hospital facilities available in their community; yet many are not fully cognizant of the nursing organizations ready and able at all times to supplement the physician's care in the hospital and in the home. Recently the Community Nursing Council, of Boston, has issued a *Handbook of Nursing Services in Boston*,* and therein is described briefly but adequately those nursing resources offered to the public through nonprofit institutions. The booklet outlines such services as those that may be had from the Household Nursing Association, equipped to give adequate care to patients with minor ailments and to convalescents at home, and the public-health nursing agencies, organized to carry out all phases of the public health program with services rendered to the individual, the family, the school or the business establishment. There is also described the Central Directory for Nurses, the purpose of which is to aid the medical profession and the public in obtaining efficient nursing care.

This handbook is primarily intended as a directory of nursing and allied services in Boston, and

as such it should be in the hands of all physicians of this vicinity. It is particularly to be noted that "practically every community has a visiting-nurse service, which provides nursing care in the home at a small charge or on a free basis for those unable to pay."

MEDICAL EPONYM

GRAVES'S DISEASE

Exophthalmic goiter was described by Robert J. Graves (1797–1853), of Dublin, in Lecture No. 12 in a series of clinical lectures delivered at the Meath Hospital during 1834–1835. The lecture is reported in the *London Medical and Surgical Journal* (II, 7: 513–520, 1835) under the following title: "Persesquinitrate of Iron in Chronic Diarrhoea—Blueness of the Fingers and Toes in Fever—Some Account of the Yellow Fever Which Prevailed in Dublin in 1827—Newly Observed Affection of the Thyroid Gland in Females: Its connexion with palpitation, with fits or hysteria—Erysipelas—Remarks on the Formation of Acidity of the Stomach in Indigestion—Psoriasis—Treatment by Arsenic." Apparently the subject was considered of relatively minor importance.

I have lately seen three cases of violent and long continued palpitations in females, in each of which the same peculiarity presented itself, viz. enlargement of the thyroid gland; When the palpitations were violent the gland used notably to swell and became distended. . . . The swelling immediately began to subside as the violence of the paroxysm of palpitation decreased. . . . In one the beating of the heart could be heard during the paroxysm at some distance from the bed. . . .

. . . . We may expect to observe the tumefaction of this gland also where the palpitation depends on organic disease of the heart, as in the following case detailed to me by a friend.

A lady, aged twenty, became affected with some symptoms which were supposed to be hysterical . . . it was observed that her pulse had become singularly rapid . . . being never under 120. . . . She next complained of weakness on exertion, and began to look pale and thin. Thus she continued for a year. . . . It was now observed that the eyes assumed a singular appearance, for the eyeballs were apparently enlarged, so that when she slept or tried to shut her eyes, the lids were incapable of closing. When the eyes were open, the white sclerotic could be seen, to a breadth of several lines, all round the cornea. In a few months, the action of the heart continuing with unceasing violence, a tumour, of a horse-shoe shape, appeared on the front of the throat and exactly in the situation of the thyroid gland.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON STATE AND
NATIONAL LEGISLATION

The following bills are scheduled for hearings at the State House during the week of March 3:

March 4

H. 122 (Public Health). Bill (accompanying House 120, recommendations of the Department of Public Health) relative to requiring the clerk or registrar of each city or town to give to persons who file notice of intention of marriage suitable information concerning gonorrhea and syphilis. This bill provides for premarital educational advice regarding genitoinfectious diseases. *Favored.*

H. 1234 (Public Health). Petition of Henry M. Landesman for legislation to require certificates from physicians that physical and blood-test examinations have been made by parties filing marriage intentions. This bill is adequately cared for by H. 122. *Opposed.*

H. 460 (Public Health). Petition of Leslie B. Cutler for legislation to regulate further the filing of notices of intention of marriage, the delivery of certificates of such intention and the return of unused certificates. This bill provides premarital educational advice and examination for genitoinfectious diseases. *Undecided* (favored in principle but opposed as drawn).

PREGNANCY IN A PATIENT WITH
RHEUMATIC HEART DISEASE

Mrs. L., a twenty-nine-year-old para II, about seven months pregnant, was sent into the hospital on August 15, 1940, because of increasing dyspnea and swelling of the ankles.

The family history was irrelevant. The patient's past history was noncontributory except for the following data directly bearing on the present illness. She had her first and only attack of rheumatic fever at nineteen years of age. Since then there had been moderate limitation of activity because of dyspnea and fatigue, but she had been able to do her own housework during seven years of married life. For two or three years before admission she had been taking digitalis most of the time because she found that this greatly reduced the dyspnea on exertion, even though the heart had a regular rhythm. Her other pregnancy ended in a miscarriage at three months a few years previously. This experience apparently had not altered her cardiac reserve.

The first six and a half months of the present pregnancy were not eventful, but two weeks before entry the dyspnea suddenly became severer, and an electrocardiogram was reported to have shown auricular fibrillation. The consultant increased the dose of digitalis, but termination of the pregnancy was not discussed. The dyspnea did not diminish, and a few days before admission the patient developed swelling of the ankles and slight nausea. During this period she had been ambulatory.

Examination on admission revealed a normally developed and well-nourished woman, sitting up in bed. There was no dyspnea at rest, and no orthopnea. The lungs were clear. The heart was slightly enlarged to percussion, and the pulmonary conus appeared to be dilated. There was a faint diastolic murmur at the apex, but no thrill. The pulse rate was grossly irregular at 90 and showed coupled beats. The blood pressure was approximately 110 systolic, 70 diastolic. The abdomen was enlarged to a size consistent with a seven months' pregnancy. There was no edema of the ankles after several hours of recumbency.

Although the dangers of allowing fibrillation to continue were realized, it was thought that the patient had probably already experienced the maximum load of the pregnancy on her circulation. It was therefore decided to allow the pregnancy to proceed for another two or three weeks, in the hope of obtaining a viable child by cesarean section, since it was believed that this would entail little more risk than immediate termination of the pregnancy. The digitalis was discontinued for two days until the signs of digitalis intoxication had subsided, and a maintenance dose of $1\frac{1}{2}$ gr. a day was then resumed. The patient was given complete bedrest, with a low-calorie diet and moderate restriction of sodium and fluids.

In spite of these measures there was a progressive increase in dyspnea, so that it was troublesome even when the patient was sitting up; her legs began to swell, even in bed. The pulse, which was about 90, was grossly irregular. No rales were heard in the lungs. On the sixth day after admission the patient was delivered by a low midline cesarean section under open-cone ether anesthesia. A viable girl was obtained, whose weight was estimated at 3 or 4 pounds. The mother stood the procedure well and showed no respiratory embarrassment at any time.

For the first five days after operation the digitalis was increased to 3 gr. a day, because the pulse had risen to 120 and was very irregular and of poor quality. On the third day the pulse, although still 120, was regular and there was no dyspnea.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

On the fifth day the pulse was regular at 80, except for occasional extrasystoles, and the digitalis was reduced to $1\frac{1}{2}$ gr. a day. The rest of the puerperium was uneventful. An electrocardiogram on the tenth day showed normal sinus rhythm except for occasional auricular extrasystoles. The digitalis was continued, however, since the patient had found, as previously noted, that she was more comfortable on a maintenance dose even with a normal rhythm. She left the hospital ambulatory on the fourteenth day after the operation. She and the baby have continued to do well, and a recent report—four months after discharge—states that she has less exertional dyspnea now than she had before the onset of the pregnancy.

Comment. This case had a fortunate outcome. A woman who for several years has had to take digitalis to carry on her daily tasks without dyspnea is not a particularly favorable risk for pregnancy. If pregnancy is undertaken, drastic reduction of daily activity must be made, or the load of pregnancy will be too much for her. In this case, at six and a half months the load of pregnancy evidently became too much for the patient, and she developed heart failure with auricular fibrillation.

In this situation, interrupting the pregnancy is now considered to be a dangerous procedure for the following reasons: there is no immediate improvement to be expected by interrupting the pregnancy; the interruption itself brings added strain on the heart at a time when the load of pregnancy is already heavy; and the load of normal pregnancy diminishes during the last few weeks. Therefore, present judgment is that it is wise not to interrupt pregnancy but to support the patient by all means until term, then allow her to have a carefully conducted normal delivery unless there are special reasons for abdominal hysterotomy. It takes a great deal of self-restraint to withhold hysterotomy in this situation, but the indications as outlined above favor this course. The decision whether or not to interrupt the pregnancy really was made before the peak load of pregnancy hit this patient. By the time the load appeared it was too late to interfere without considerable risk.

The death rate in auricular fibrillation in pregnancy in women with rheumatic heart disease is approximately 33 per cent. This includes all cases, whether interrupted or not. Undoubtedly, interruption early in pregnancy would save many maternal lives in such cases, but it should be done early.

NORFOLK MEDICAL NEWS

For many years the *Worcester Medical News* has served a useful and extremely valuable function in presenting to the members of the Worcester District Medical Society matters of local and general medical interest. It has gradually increased in size, and there is no doubt that news bulletins of this sort are extremely popular with the members of a district society of appreciable size.

The Norfolk District Medical Society, appreciative of the value of such bulletins, voted at its January meeting to publish a bulletin, and the first issue of the *Norfolk Medical News* was recently forwarded to the 900 members of the society. The editor is Dr. Carl Bearse, and the associate editors, Drs. J. C. V. Fisher, David Halbersleben, I. R. Jankelson, C. J. E. Kickham and Kathlyne S. Snow. The *Journal* welcomes the publication and extends best wishes for the continuance of its initial success.

POSTGRADUATE EXTENSION COURSES

The postgraduate extension courses are sponsored by the Massachusetts Medical Society in cooperation with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau. Registration is free to all legally registered physicians of the Commonwealth. For further information the district chairman of postgraduate instruction should be consulted.

The programs for the spring sessions are as follows:

BERKSHIRE DISTRICT: PITTSFIELD

SUBJECT	DATE
Recent Advances in Medical Therapeutics:	
Sedatives; analgesics; cathartics; sulfanilamide compounds; dangerous drugs	March 6
Infections of the Hands and Feet	March 13
Dermatitis and Eczema (see below for questions to be discussed)	March 20
Chemotherapy in the Treatment of Gonococcal Infection	March 27
Diagnosis, Treatment and Prognosis of Central-Nervous-System Syphilis	April 3
Pediatric Case Discussions	April 10
Management of Abdominal Distention	April 17
Obstetric Infections: Diagnosis and treatment	April 24

Meetings to be held at the Bishop Memorial Building, Thursdays, at 4:30 p.m.

Harry G. Mellen, M.D., Chairman
150 North Street, Pittsfield

BRISTOL SOUTH DISTRICT: FALL RIVER

SUBJECT	DATE
Diagnosis, Treatment and Prognosis of Central-Nervous-System Syphilis	March 11

Recent Advances in Medical Therapeutics Sedatives, analgesics, cathartics, sulfanil amide compounds, dangerous drugs	March 18
Obstetric Complications with Case Histories and Clinical Problems	March 25
Acute Abdominal Pain Its interpretation and management	April 1
The Clinical Recognition of the Types of Jaundice and Recent Advances in Their Treatment	April 8
Chemotherapy in the Treatment of Gonococcal Infection	April 15
Diagnosis and Treatment of Minor Lesions of Rectum and Anus	April 22
Pediatric Case Discussions (patients will be shown)	April 29
Meetings to be held at the Union Hospital, at 4 30 p.m.	Tuesdays,

Howard P Sawyer, M.D., *Chairman*
68 Bigelow Street, Fall River

FRANKLIN DISTRICT GREENFIELD
